The usually proposed functions (S_a) are based on (1) simplified expressions for the evaluation of the floor acceleration and (2) simplified shape functions representative of the required FRS.

It is worth mentioning that given a structure, knowing of it (1) the prevalent modal shape (Φ), (2) the prevalent period (T_s), and (3) the modal participation factor (Γ) if a seismic action is considered, the absolute structural acceleration ($\ddot{u}_i$) associated to the single modal coordinate (Φ_i) can be evaluated according to Eq. 3 where $R_S(T_s)$ is the value of the normalized acceleration spectrum, for a given value of the structural damping (ζ_s) at the prevalent period of the structure.

$$\ddot{u}_i = \text{PGA} \cdot \Gamma \cdot \{1 + [R_S(T_s) - 1] \cdot \Phi_i\} \quad (3)$$

Assuming a given analytical function (R_{FRS}), being it dependent on the period (T_{NS}) and the damping (ζ_{NS}) of the nonstructural element, the required FRS, associable to the Φ_i modal coordinate, is equal to

$$\text{FRS}_i = \text{PGA} \cdot \Gamma \cdot \{1 + [R_S(T_s) - 1] \cdot \Phi_i\} \cdot R_{FRS} \cdot (T_{NS}) \quad (4)$$

Usually, Eq. 4 is simplified adopting (1) a constant value for $R_S(T_s)$ evaluated at the plateau of the acceleration spectrum (assumed in the range

of 2–3), (2) a simplified expression for the evaluation of modal displacement Φ_i of a given floor supposed to be equal to z/H where z is the level of the considered floor and H is the total construction height, and (3) a value of Γ between 1 and 1.5.

Based on the previous assumptions, Eq. 4 can be simplified as follows, having assumed $R_S = 3$, $\Gamma = 1$:

$$\text{FRS}_i = \text{PGA} \cdot \Gamma \cdot [1 + 2 \cdot (z/H)] \cdot R_{FRS} \cdot (T_{NS}) \quad (5)$$

In the following sections, some literature expressions (CEN 2008; FEMA 369 2001; AFPS 2007; KTA 2012) will be given, expressing them in terms of the normalized FRS (S_a) that corresponds to FRS_i evaluated for $\text{PGA} = 1$.

It has to be specified that in order to show the trend of the S_a functions, they will be plotted, contextualizing it to the simple structure described in the Case Study section.

CEN (2008)

The following Eq. 6, plotted in Fig. 7, is proposed, supposing $\zeta_s = \zeta_{NS} = 5\%$.

$$S_a = 3 \cdot \frac{1 + \frac{z}{H}}{1 + \left(1 - \frac{T_{NS}}{T_s}\right)^2} - 0.5 \geq 1 \quad (6)$$

Equation 6 can be evaluated assuming $T_{NS} = 0$, obtaining (1) the value of the expression

Secondary Structures and Attachments Under Seismic Actions: Modeling and Analysis,
Fig. 7 Amplification factor S_a for different values of z/H

Secondary Structures and Attachments Under Seismic Actions: Modeling and Analysis,

Fig. 8 Amplification factor (S_a) shape versus T_{NS}/T_N

adopted for the evaluation of the normalized floor acceleration (Eq. 7a) and (2) the value of the adopted expression for the evaluation of R_{FRS} (Eq. 7b). So that Eq. 6 can be rearranged as reported in Eq. 7c.

It is possible to recognize that (1) a value of 2.5 has been assumed for the evaluation of R_s and (2) the expression adopted for the evaluation of R_{FRS} is supposed to be dependent on the normalized floor height.

$$\frac{\ddot{u}_i}{PGA} = \left\{ 1 + [R_s(T_s) - 1] \cdot \frac{z}{H} \right\} = 1 + 1.5 \cdot \frac{z}{H} \quad (7a)$$

$$R_{FRS} = \frac{1 + \frac{z}{H}}{1 + 1.5 \cdot \frac{z}{H}} \cdot \frac{3}{1 + \left(1 - \frac{T_{NS}}{T_s}\right)^2} - \frac{0.5}{1 + 1.5 \cdot \frac{z}{H}} \quad (7b)$$

$$S_a = \left(1 + 1.5 \cdot \frac{z}{H} \right) \cdot \left\{ \frac{1 + \frac{z}{H}}{1 + 1.5 \cdot \frac{z}{H}} \cdot \frac{3}{1 + \left(1 - \frac{T_{NS}}{T_s}\right)^2} - \frac{0.5}{1 + 1.5 \cdot \frac{z}{H}} \right\} \geq 1 \quad (7c)$$

FEMA 369 (2001)

The following Eq. 8, plotted in Fig. 8, is proposed supposing $\zeta_s = \zeta_{NS} = 5\%$, where the values of R_{FRS} are reported in Table 3:

$$S_a = \left(1 + 2 \cdot \frac{z}{H} \right) \cdot R_{FRS} \quad (8)$$

Secondary Structures and Attachments Under Seismic Actions: Modeling and Analysis, Table 3 Values of R_{FRS} as function of T_{NS}/T_N

T_{NS}/T_N	R_{FRS}
$T_{NS}/T_N < 0.5$ and $T_{NS}/T_N > 2.0$	1.0
$0.7 \leq T_{NS}/T_N < 1.4$	2.5
$0.5 \leq T_{NS}/T_N < 0.7$	$(7.5 \times T_{NS}/T_N) - 2.75$
$1.4 \leq T_{NS}/T_N < 2.0$	$6 - (2.5 \times T_{NS}/T_N)$

It is possible to recognize that (1) a value of 3.0 has been assumed for the evaluation of R_s and (2) the expression adopted for the evaluation of R_{FRS} is supposed to be independent on the normalized floor height.

AFPS (2007)

The following expression is proposed:

$$S_a = \sqrt{1 + \Gamma_s^2 \cdot R_s^2} \cdot \left(\frac{z}{H} \right) 2\alpha \cdot R_{FRS} \quad (9)$$

where (1) α is a parameter to be calibrated in order to minimize the difference between the effective modal displacements (Φ_i) and the proposed simplified expression (z/H), (2) R_s is the value of the normalized structural acceleration evaluated at the fundamental structural period (T_s) for a considered value of the structural damping, (3) the participation factor (Γ_s), evaluable according to Eq. 10a, assumes a

maximum value of 1.6, if $\alpha = 1.5$ is imposed, and (4) R_{FRS} values are reported in Table 3 as a function of parameter A (see Eq. 10b) that takes into account the damping (ζ_{NS}) of the nonstructural element.

$$\Gamma_S = \frac{2\alpha + 1}{\alpha + 1} \tag{10a}$$

$$A = \frac{35}{2 + \zeta_{NS}} \tag{10b}$$

It is worth mentioning that Eq. 9 derives from Eq. 4, with the following assumptions: (1) a unitary participation factor is considered for the ground acceleration, while the principal mode participation factor is considered according to Eq. 10a. (2) The spectral acceleration $R_s(T_s)$ is considered for the evaluation of the floor relative acceleration instead of the spectral relative normalized acceleration ($R_s(T_s) - 1$). (3) The ground acceleration and the relative structural acceleration are combined through the SRSS (Square Root of the Sum of the Squares) combination rule (Table 4 and Fig. 9).

KTA (2012)

The proposed expression does not give any information to evaluate the floor acceleration (a_g), but it only defines the amplification shape (R_{FRS}) reported in Fig. 10 (left), where the f -axis is the component frequency axis (in logarithmic scale) and f_1 , f_n , and f_{limit} , respectively, are (1) lowest decisive eigenfrequency of the principal system

at the lower limit value in the variation range of the system parameters, however, not lower than the rightmost corner frequency of the highest plateau of the associated response spectrum; (2) highest decisive eigenfrequency of the principal system for the upper limit value in the variation range of the component parameters, however, not lower than the rightmost corner frequency of the highest plateau of the associated response spectrum; and (3) upper limit frequency of the associated response spectrum.

The maximum value of the amplification factor is reported in Fig. 10 (right), where D_1 and D_2 are respectively the damping ratios (in percentage of critical damping) of structural and nonstructural elements whose suggested values are reported in Table 5.

In order to compare the obtainable FRS with those previously discussed, the amplification factor (S_a) is plotted in Fig. 11, having assumed (1) a 5 % damping for both structural and nonstructural

Secondary Structures and Attachments Under Seismic Actions: Modeling and Analysis, Table 4 Values of R_{FRS} as function of T_{NS}/T_N

T_{NS}/T_N	R_{FRS}
$T_{NS}/T_N < 0.5$ and $T_{NS}/T_N > 2.0$	1.0
$2/3 \leq T_{NS}/T_N < 3/2$	A
$0.5 \leq T_{NS}/T_N < 1.5$	$A - (A - 1) \times \frac{(\log_3^3 T_{NS})}{(\log_4^3)}$
$2 < T_{NS}/T_N$	$K_T = A - (A - 1) \times \frac{(\log_3^2 T_{NS})}{(\log_5^2)}$

Pipes	4	2
Steel with welded connections and welded components (e.g., vessels, valves, pumps, motors, ventilators) ^a	4	2
Steel with SL or SLP bolt connections (<i>SL</i> – structural bolt connection with a borehole tolerance ≤ 2 mm; <i>SLP</i> – fitted bolt connection with a borehole tolerance ≤ 0.3 mm)	7	4
Steel with SLV(P) or GV(P) bolt connections (<i>SLV(P)</i> – preloaded fitted bolt connection; <i>GV(P)</i> – fitted friction-grip bolt connection)	4	2
Cable support structures	10 ^b	7
Fluid media	0.5	0.5

^aIf, on account of the design, deformations are possible only in small regions of the structure (low structural damping), the values as listed shall be halved (special cases)

^bIn well-substantiated cases, the damping ratio may be increased up to 15 %

elements, (2) the FEMA expression (see Eq. 11) for the evaluation of the normalized floor acceleration, (3) $f_1 = 6.66$ Hz that is the rightmost corner frequency of the acceleration plateau of CEN (2008) type 1 Spectrum (A soil), and (4) $f_n = 11.1$ Hz that is the highest decisive eigenfrequency of the principal system described in the Case Study section.

$$a_g = 1 + 2 \cdot \frac{z}{H} \tag{11}$$

Verification

As stated in KTA (2012), the verification process has to regard (1) the load-carrying capacity in terms of strength, stability, and secure positioning (e.g., their protection against falling over, dropping down, impermissible slipping); (2) the integrity, that is, the capability of a component above and beyond its load-carrying capacity to meet the respective requirements regarding leak tightness and deformation restrictions; and (3) the functional capability, that is, the capacity of a system or component above and beyond its load carrying capacity to fulfill the designated tasks by way of its respective mechanical or electrical function.

Secondary Structures and Attachments Under Seismic Actions: Modeling and Analysis,
Fig. 11 Normalized floor acceleration based on Eq. 11

Depending on the importance of the element to verify and the material (conventional or nonconventional material), the verification process could include experimental tests either for the validation of the numerical model or for the qualification of the element itself. The verification procedure can include a) analysis, b) physical experiments, and c) analogies and plausibility considerations.

Based on the introduced classification that distinguishes secondary element in structural and nonstructural, the following criteria can be defined:

1. Secondary structural elements have to be verified with regard to the vertical loads transmitted from the P structure, opportunely combined with the other action considered to be contemporary to the seismic action. The connections have to be verified with regard to the seismic-induced action, including second-order effects such as those induced by the axial load in the deformed configuration (P- Δ effects).
2. Secondary nonstructural elements have to be verified with regard to the self-weight loads opportunely combined with the other actions considered to be contemporary to the seismic action.
3. For both types of elements (S and NS elements), the action supposed to act contemporary with the seismic action can be consequent to different events such as those pertaining to collisions, explosions, and fires.

The verifications have to consider potential damage induced to other elements, which loss of capacity could induce either human or economic loss.

The verification is performed checking that the element capacity will be greater than the demand, defined in terms of different mechanical properties (stresses, forces, displacement) depending on the adopted materials.

In order to define the design forces, the considered floor response acceleration spectra can be reduced to take into account the nonstructural element ductility. If the FRSs have been numerically evaluated, they have to be modified (see Fig. 12) to take into account the structural stiffness uncertainties: (1) an adequate plateau has to be imposed in correspondence of the structural period, (2) the linear envelope has to be properly introduced, and (3) the ductility of the nonstructural element can be considered, properly reducing the FRS (see Fig. 12b, c).

Case Study

The previously described procedures to determine FRSs will be applied to a steel frame system hosting a set of equipments, whose characteristics and localization are reported in Table 6 and Fig. 13 (left), reproduced from KTA (2012).

The maximum acceleration of each equipment can be evaluated by means of (1) time histories considering the interaction between the principal structure and the equipment or (2) FRSs

9,10		15	5	0.036

evaluated based on the previously described *cas-cade* procedure or on the predictive expressions already presented.

Time History-Based Evaluation of Equipment Accelerations

A detailed model of the PS system could include the secondary system modeled as reported in Fig. 13 (right): PS principal modal shapes are those reported in Fig. 14a. Alternatively equipments can be modeled by means of mass lumped at pertinent position of the floor as reported in Fig. 13 (center): PS principal modal shapes are those reported in Fig. 14b.

Both models have been analyzed by means of time histories, carried out (1) generating 7 accelerograms compatible with the acceleration spectra ($PGA = 0.15\text{ g}$) suggested in CEN (2008) for B soil and low-magnitude events ($M < 5.5$) (see Fig. 15), (2) considering a constant damping value of 2 % for the structural model and for the

equipments, (3) performing a dynamic modal TH analysis evaluating, for each accelerogram, the maximum absolute value of a given quantity (acceleration), and (4) averaging the maximum values obtained (at step 3) for each analysis.

If the detailed model with interaction (WI) is considered, the evaluated quantities are the mass accelerations of the single equipment.

Regarding to the lumped mass system, (1) for each considered accelerogram, an FRS has been generated (Fig. 16a): the FRS is relative to the acceleration of the top left floor corner (no sensible variations in FRSs have been observed if other floor points are considered); (2) having generated (for each floor) seven FRSs, the averaged FRS has been evaluated (Fig. 16b); and (3) for each equipment, depending on the floor it is attached to and its period (T_{NS}), the acceleration has been evaluated through the resulting FRS.

The results of the performed evaluation are reported in Table 7 where the acceleration of each floor and the acceleration of each equipment are reported, calculated with or without interaction.

Comparing the maximum acceleration evaluated considering the PS system with those evaluated through the cascade procedure, a significant difference (if the Equipment 2 is concerned) between the two approaches can be noticed: the difference is aspecktable since the equipment period (0.093 s) is close to the period of the third modal shape (0.090 s) so that (see Fig. 16c) in a very small period range (in between 0.09 and 0.1 s), the acceleration ranges between 7.0 and 4.5 m/s – the already-mentioned *tuning* effect causes the equipment acceleration reduction if the complete PS system is analyzed in order to include the P-S interaction.

Analytical FRS-Based Evaluation of Equipment Accelerations

It has been already outlined that CEN proposal (CEN 2008) and FEM proposal (FEMA 369 2001) are based on a fixed value (5 %) of structural and equipment damping. So that only the proposal reported in AFPS (2007) and KTA (2012) will be considered in the following.

Secondary Structures and Attachments Under Seismic Actions: Modeling and Analysis, Fig. 13 Case study: geometry (left) and models (center, right)

Secondary Structures and Attachments Under Seismic Actions: Modeling and Analysis, Table 7 Floor acceleration (FA, m/sec^2) and equipment acceleration evaluated without (F_w/o) and with (F_w) interaction

N_E	N_F	Floor acceleration	FRS W/o	FRS W
1	1°	2.21	2.7	2.1
2	1°	2.21	6.5	3.2
3	2°	3.26	4.20	4.0
4	2°	3.26	4.20	4.0
5	2°	3.26	4.20	4.0
6	3°	3.65	3.70	3.8
7	3°	3.65	5.10	3.8
8	4°	4.28	4.30	4.3
9	5°	5.25	5.3	5.3
10	5°	5.25	5.3	3.3

It has to be specified that (1) concerning the KTA (2012) proposal, the floor acceleration evaluated by means of TH analyses (see Table 7) has been considered and (2) concerning the AFPS (2007) proposal, the FRSs have been evaluated by means of Eq. 9, evaluating the spectral acceleration corresponding to the first structural period (0.49 s) and a participation factor (Γ_S) equal to 1.6 that correspond to $\alpha = 1.5$ (see Eq. 10a).

It is clear (see Fig. 17a, b) that considering equipment periods close to the lowest structural periods, the KTA proposed expressions are more conservative while the AFPS expressions are less conservative (Tables 8 and 9).

Summary

The chapter deals with the methodologies focused on the seismic analyses of the so-called *secondary* (sometimes *attachments*) elements that are part of a construction whose seismic resistance is delegated to a *primary* resistant structure.

Although secondary elements can be decontextualized from the primary resistant structures, they will be subjected to seismic action as well and, having their own structures, need to be modeled and analyzed by means of methods included in the general methodologies proper of seismic branch.

Among the methodologies usually adopted for secondary element analyses, the Floor Response Spectra (FRS)-based analyses become popular due to their recognized simplicity.

FRSs provide acceleration (consequently velocity and displacement) to which the

secondary element (with a given period and damping) will be subjected to when *attached* (from which the alternative name *attachments* derives) to a given part of the structures such as a building floor (from which the name Floor Response Spectra derives).

Given that FRS generation could require onerous numerical analyses, simplified expressions are proposed in literature and discussed in the following together with the general methodologies tailored to secondary element modeling and seismic analyses.

Synonyms

Broadband seismometers; Force-balance accelerometers; MEMS accelerometers; Passive seismometers; Seismic recorders; Servo-accelerometers; Strong ground motion

Introduction

Earthquake ground motion ranges in amplitude from a few nanometers (e.g., for a distant earthquake or a local microearthquake) to several meters close to the fault causing a big quake. It is very difficult to record that wide range of signals with a single type of instrument. Seismometers are designed to be very sensitive for detecting weak signals of ground motion and have a response proportional to ground velocity in a frequency band typically from 0.01 to 100 Hz. On the other hand, strong ground motion instruments are in general less sensitive and may manage on scale large ground motion amplitudes. This strong ground motion may reach peak accelerations above 2 g (g is gravity acceleration) and peak velocities higher than 3 m/s (Anderson 2010). The motion experienced at specific points in a building or structure may be even higher. Seismic accelerometers were developed for recording on scale vibrations up to such range of amplitude either on ground or in structures.

Due to instrumental and practical reasons, the preferred motion measure for strong ground motion is acceleration, since the inertial force acting on a structure due to a seismic action is proportional to ground acceleration. Nevertheless, some strong-motion velocimeters are commercially available, but their use is much less widespread.

Weak motion from local small earthquakes or moderate to strong earthquakes at regional or large distances are studied fundamentally on seismograms, proportional to ground velocity in a wide frequency band. However, even for strong motion, ground velocity and displacement are also of interest: Ground velocity is directly related to important parameters such as shake energy or soil liquefaction potential and is linked to damage on intermediate period structures and buried pipelines (e.g., Akkar and Bommer 2007). Ground displacement is significant for large structures, where differential displacements may cause damage, and from a seismological view, it is proportional to seismic moment, a source parameter defining the earthquake size. Therefore, it is desirable that velocity and displacement may be estimated from acceleration records.

Historical Overview

This section partly follows the review article by Trifunac (2009). See also “► [Historical Seismometer](#).”

Earlier attempts to record strong ground motion were made with the so-called seismoscopes (Fig. 1), most of which were limited to record the horizontal ground motion on a (curved) surface without a time reference. These instruments consisted of a pendulum, either normal or inverted, whose mass motion was drawn on a curved surface (usually a smoked glass) by a stylus.

As a result of the program of strong-motion earthquake investigation of the US Coast and Geodetic Survey and cooperative institutions (McComb and Ruge 1937), the first instrument designed to record the strong ground motion versus time was developed in the decade of 1930.

Seismic Accelerometers, Fig. 1 Simplified schematics of a seismoscope. A mass is suspended from the frame by a wire, and a stylus writes the relative motion on a spherical cap surface

This instrument was built with a mass suspended on torsion wires, based on the Wood-Anderson seismometer principle (known because it was used by Richter to define his magnitude scale). Damping was achieved – like for the Wood-Anderson seismometer – using a conductive copper mass in which the field of a permanent magnet induced parasitic currents. A more robust pivoted suspension and a spring were later incorporated. Recording was made on photographic paper on a drum, with a “starter” system built with an independent undamped pendulum closing an electric contact when a strong motion occurred. A clock mechanism interrupted the light beam to produce time marks on the record. The first strong ground motion accelerograms were obtained on three stations in 1933 from the Long Beach earthquake (McComb and Ruge 1937).

With analog records and the computational means available at that epoch, it was very difficult to estimate displacement from acceleration. Therefore, some seismometers with unity amplification and photographic recording were used to obtain displacement records (see “► [Passive Seismometers](#)”).

A remarkable effort was made to test these first instruments with a shaking table to assess the independent motion of the components, zero shifts (instability of the mass rest position),

parasitic vibrations (instrument vibration modes different from fundamental), the ability to calculate velocity and displacement from acceleration records, and other features (McComb and Ruge 1937, Ruge and McComb 1943).

It was not until early 1960 that accelerographs become commercially available. Around that time the digital computation also made it possible to calculate the velocity and displacement histories from the corresponding accelerograms. In this decade, some seismic accelerometers were still of torsion wire or inverted pendulum types, but the first servo-accelerometers using the concept of force balance appeared (Reasenberg 1969; Eisenberg and McEvilly 1971). This concept (see later) is to apply a feedback force on the mass to keep it at rest relative to the ground. So the applied force is the mass times the ground acceleration. The main advantages are improved linearity and dynamic range (i.e., the relation between the maximal non-clipped signal amplitude and the minimal resolvable amplitude; see later). Recording was analog on photographic paper, but some prototypes used digital recording (Reasenberg 1969). The first digitizers used, however, had a too low resolution to match the dynamic range of servo-accelerometers.

Following the period of photographic recording, some models adopted analog recording on magnetic tape using frequency modulation, but digital recording was soon the norm due to its better characteristics. Presently all high-performance seismic accelerometers use force-balance sensors and high-resolution digital recording.

Basic Principles of Accelerometers

Seismometers and accelerometers are both based on the inertia principle.

In Fig. 2, a schematic view of the well-known passive damped oscillator is drawn. A mass m is fixed to one end of a spring of elastic constant k . The other end of the spring is fixed to a frame anchored to the ground. The motion is mechanically limited to the horizontal axis shown. When the ground moves a displacement

Seismic Accelerometers, Fig. 2 A schematic single degree of freedom oscillator. A spring makes a force proportional and opposed to the relative displacement of the mass $z(t)$, and a dashpot damps this motion with a force proportional to the relative velocity. The ground (and the frame) displacement is $u(t)$

$u(t)$ with respect to some inertial frame, the mass displacement is $y(t)$ in this inertial frame, and $z(t) = y(t) - u(t)$ is the mass displacement relative to the instrument casing or the ground. A dashpot represents a damping device (usually magnetic) that acts on the mass with a force proportional to its relative velocity. This damping avoids the oscillation of the system with its free period when it is excited. The two real forces acting on the mass are the spring force and the damping force, so the dynamics equation is (Havskov and Alguacil 2010)

$$-k \cdot z - d \cdot \dot{z} = m \cdot y(t) = m[\ddot{u}(t) + \ddot{z}(t)] \quad (1)$$

It is useful to write the equation as a function of the two coefficients experimentally measurable. The free or natural angular frequency ω_0 can be defined as

$$\omega_0 = \sqrt{\frac{k}{m}} = 2\pi f_0 = \frac{2\pi}{T_0} \quad (2)$$

where T_0 is the suspension-free period and its inverse f_0 is the natural frequency. The damping coefficient or damping fraction h is

$$h = \frac{d}{2\omega_0 m} \quad (3)$$

Rearranging Eq. 1 then gives

$$\ddot{z}(t) + 2h\omega_0 \cdot \dot{z}(t) + \omega_0^2 \cdot z = -\ddot{u}(t) \quad (4)$$

Both ω_0 and h can be measured, e.g., from the system transient response or by exciting the system with steady-state harmonics of frequencies in a band including f_0 . For low frequencies, the mass velocity and acceleration terms in Eq. 4 are small, so mass displacement z is then proportional to the ground acceleration $\ddot{u}$.

The system response may be characterized in the Laplace transform domain. Let $Z(s)$ and $U(s)$ be the Laplace transforms of $z(t)$ and $u(t)$. By assuming null velocities and displacements at initial time, the Laplace transform of Eq. 4 becomes

$$s^2 Z(s) + 2h\omega_0 s Z(s) + \omega_0^2 Z(s) = -s^2 U(s) \quad (5)$$

The transfer function between the mass relative motion Z and the ground acceleration $s^2 U$ is then

$$T_a(s) \equiv \frac{Z(s)}{s^2 U(s)} = \frac{-1}{s^2 + 2h\omega_0 s + \omega_0^2} \quad (6)$$

The explicit frequency response function is obtained by substitution of s by $i\omega$ in Eq. 6, that is,

$$H_a(\omega) = \frac{-1}{-\omega^2 + 2h\omega_0 \cdot i\omega + \omega_0^2} \quad (7)$$

For a sinusoidal motion of arbitrary frequency $f = \omega/2\pi$, the modulus of this complex function represents the amplitude relation between the mass relative motion $z(t)$ and the ground acceleration $\ddot{u}(t)$, and its phase is the relative phase between them. Both are plotted in Fig. 3 as functions of frequency. The amplitude response is flat for acceleration up to the corner frequency f_0 and decays at higher frequencies as f^{-2} . The frequencies of interest are usually in the flat zone, so the instrumental correction for amplitude is simply a constant factor. Observe, nevertheless, that the phase response deviates from flatness even for frequencies well under the natural frequency. This response function is formally like the response of a second-order low-pass filter with cutoff frequency $f_0 = \omega_0/2\pi$.

Seismic Accelerometers,

Fig. 3 *Top*: amplitude response of a mechanical accelerometer for ground acceleration. *Bottom*: phase response. The free period is $T_0 = 0.02$ s ($f_0 = 50$ Hz) and $h = 0.70$

Displacement Transducer

The mass motion has to be measured and recorded by some device. In early accelerometers, a light beam was reflected in a mirror which rotated with the mass motion. Presently, almost all seismic accelerometers use a capacitive transducer, which gives a voltage output proportional to the mass displacement. This type of transducer is very sensitive – it can resolve displacements of the order of pm (10^{-9} mm).

Two types of capacitive transducers may be used: variable gap or variable area. The most used arrangement, Fig. 4, is a pair of capacitors with a common central moving plate and two fixed plates or vice versa (variable gap). When the central plate moves with the mass relative to the fixed plates, one of the capacities increases and the other decreases. The same happens with the variable area type. An identical sinusoidal or square signal with frequency of several kHz is fed to each capacitor with opposite sign. The signal amplitude at the common point of both capacitors is proportional to the capacitance

difference, and the phase depends on the sign of this difference. This may be demodulated with a phase-sensitive demodulator (PSD) circuit. While this is the most used technique, other approaches are possible.

The output of the detector is proportional to the capacitance difference. Let A be the overlapping area between plates and d the distance (gap) between them. If d is much smaller than the plate dimensions, the capacitance of a parallel plane capacitor is

$$C = \frac{\varepsilon \cdot A}{d} \quad (8)$$

where ε is the dielectric permittivity (for air $\varepsilon = 8.85 \cdot 10^{-3}$ pF/mm). In the variable gap transducer, for a displacement x of the central plate, it may be easily shown that the capacitance difference is

$$C_1 - C_2 = \varepsilon \cdot A \cdot \frac{2x}{d^2 - x^2} \quad (9)$$

which is not linear with x .

Seismic Accelerometers, Fig. 4 Schematics of variable capacitance displacement transducers. (a) Variable gap. As the central plate (red) moves right, the gap with the left fixed plate (blue) increases (capacitance of left capacitor, yellow, decreases), and the gap with the right plate (blue) decreases (capacitance of the right capacitor, light blue,

increases). (b) Variable area. The effective area of each capacitor (same colors as in a) varies in opposite sense when the central plate (red) moves horizontally. The gap is not at scale, since in practice it is very narrow in relation to plate dimensions. (c) Circuit schematics, see text

Seismic Accelerometers,

Fig. 5 Normalized sensitivity of capacitive transducers of variable gap (blue) and variable area (red). A straight line is plotted for reference (dotted) with the slope of the variable gap at the origin

Seismic Accelerometers, Fig. 6 Block schematic of an FBA

In a variable area transducer with plate overlap dimensions $a \times b$, the capacitance difference is linear with the displacement x :

$$C_1 - C_2 = \frac{\epsilon}{b} \cdot 2b \cdot x \quad (10)$$

In Fig. 5, these functions – excluding ϵ – are plotted for an overlapping area of $A = 100 \text{ mm}^2$ and gap distance of $d = 1 \text{ mm}$ and 0.5 mm for variable gap and variable area, respectively. Two features are clear: variable gap type is more sensitive but nonlinear, and variable area type is less sensitive but linear.

Variable gap transducers are often used in feedback systems, like force-balance accelerometers, since the mass displacement is held very small – within the linear zone – by the servo control.

Variable area transducers are used in some micro-electro-mechanical (MEM) accelerometers (see later) without feedback.

The Force-Balance Accelerometer (FBA)

Most present seismic accelerometers are of the force-balance type. The principle is to apply a feedback force on the inertial mass opposed to its motion, in such a way that this motion is reduced to a minimum. A simplified block schematic is shown in Fig. 6.

The ground acceleration produces an inertial force on the mass, like in the basic passive accelerometer of Fig. 1. The relative mass motion z is sensed with a displacement transducer, whose output is amplified, with a total factor D (volt/meter, V/m). The amplifier output v_o is applied

Seismic Accelerometers, Fig. 7 Several responses relative to ground acceleration. See text. Note the different units for each curve

through a resistor R to a force transducer (normally a coil-magnet system) with constant c (newton/ampere, N/A). The feedback force $-c \cdot v_o/R = -c \cdot A \cdot z/R$ is then applied to the mass. Equation 1 has now to be modified to

$$-k \cdot z - d \cdot \dot{z} - \frac{Dc}{R} \cdot z = m[\ddot{u}(t) + \ddot{z}(t)] \quad (11)$$

It is clear that the effect of feedback is to increase the effective stiffness of the system from k to $k + D \cdot c/R$. Arranging terms of Eq. 11 to get the form of Eq. 4, it is found that with feedback, a new effective “free” angular frequency is ω_f

$$\omega_f = \sqrt{\frac{k + D \cdot c/R}{m}} = \sqrt{\omega_0^2 + \frac{D \cdot c}{R \cdot m}} \quad (12)$$

which is higher than the “open-loop” free angular frequency ω_0 .

On the other hand, the new damping coefficient with feedback h_f is decreased to

$$h_f = h \frac{\omega_0}{\omega_f} \quad (13)$$

This is not desirable, since a low damping will produce a ringing transient response or even an unstable system. The frequency response (Fig. 7) has the same form as Eq. 7, but in this case it will show a resonance peak.

Actually, the phase-sensitive demodulator (PSD) associated with the displacement transducer will often include a low-pass filter at frequencies above the seismic band, thus introducing an additional phase delay in this band.

Some additional circuitry is then required to improve the transient response and prevent a possible self-oscillation of the servo system. Several techniques for this are possible. A simple one consists of including a second feedback loop to add a small force proportional to the time derivative of the mass displacement, i.e., the mass velocity. This allows the feedback force to control the mass motion “in advance,” and the servo loop is stabilized.

Figure 7 shows the responses relative to ground acceleration of several systems and output points of the systems. An under-damped mechanical accelerometer (without feedback

force) is drawn in curve *a*, in this example with a free oscillation frequency of 10 Hz. Curve *b* corresponds to an FBA built with this system by adding a displacement transducer and a feedback force proportional to the mass displacement, which increases the resonance frequency. The damping is still too low and a strong resonance peak at 200 Hz appears. Curve *c* shows the voltage output response for the same FBA once stabilized by the addition of a small feedback force proportional to the mass velocity. Curve *d* shows the feedback acceleration response (i.e., the feedback force per unit mass), which is nearly equal to the ground acceleration (so the amplitude response is 1) up to the frequencies around the resonance, where the feedback force needs to be a little higher to stabilize the motion. Curve *e* plots the mass motion response measured in microns (μm) relative to ground acceleration in m/s^2 . It is approximately 0.6 in the useful band, so a ground acceleration of 1 g will produce a mass motion of $9.8 \text{ m} \cdot \text{s}^{-2} \cdot 0.6 \mu\text{m}/(\text{m} \cdot \text{s}^{-2}) \approx 6 \mu\text{m}$, a very small displacement, for which the capacitive transducer will be quite linear.

It is also illustrative to view the transient response of the FBA (Fig. 8). The input is a simulated ground acceleration pulse of 1 m/s^2 and with duration of 50 ms. It can be seen that the output voltage has only a small overshoot, due to the compensation circuit in the feedback. So, there is an unavoidable small distortion affecting the higher frequencies, like any instrument with a

limited bandwidth, but this will not affect the band of interest. The feedback acceleration has a little overshoot to counteract the resonance and keep the mass as stationary as possible. The mass displacement is also shown (with sign changed) and has an amplitude about $0.6 \mu\text{m}$, as predicted by the frequency response in Fig. 7.

The FBA principle is the basis not only of servo-accelerometers but also of [broadband seismometers](#) (BB). These instruments have a flat frequency response for ground velocity in a band from ~ 0.01 to several tens of Hz. The feedback loop keeps the mass almost at rest relative to the ground, but the signal is integrated in the loop, and the output is taken from a point where it is proportional to ground velocity in a wide band. For more details, see the entry “[Principles of Broadband Seismometry](#).”

Characteristic Parameters of Accelerometers

The performance of a seismic accelerometer may be characterized by several parameters.

Sensitivity: The relation between the voltage output and the input acceleration in V/m/s^2 or V/g (gravity normal acceleration = 9.807 m/s^2). Typical values are 0.5–5 V/g .

Input Full Scale (FS): The maximum ground acceleration before the instrument gets saturated. A large FS prevents saturation with strong ground

Seismic Accelerometers,

Fig. 8 Transient response of the example FBA (Fig. 7) for a pulse in acceleration input of $1 \text{ m} \cdot \text{s}^{-2}$

motion but at a cost of sensitivity. In general, for accelerometers to be installed in zones where large ground motion is expected, FS should be 2–4 g, but in low-moderate seismicity areas, 0.5–1 g would be suitable. Nevertheless, it should be kept in mind that some of the largest peak ground motions ever recorded (up to 4.36 g for Iwate-Miyagi 2008 earthquake; Yamada et al. 2009) have been produced by moderate-size earthquakes (Anderson 2010). Some accelerometers allow user setting its FS.

Resolution: It is the minimum acceleration amplitude that it may measure. In early accelerometer digital recorders, it was limited by the digitizer (A/D converter) resolution. In modern instruments, the digitizer is usually 24 bit, and the resolution is related to the self-noise level of both the accelerometer and the digitizer. So it is usually given as self-noise level, or it may be obtained from the dynamic range. Good-quality accelerometers have noise levels under $1 \mu\text{m/s}^2$ rms (root mean square).

Dynamic Range: The relation (expressed in decibels, dB) between the maximum acceleration amplitude (FS) and the resolution. A ratio between two amplitudes a_1 and a_2 expressed in dB is $20 \cdot \log(a_1/a_2)$; for energy or power ratios, a factor 10 instead of 20 is used. The best accelerometers now have a dynamic range up to more than 150 dB, which means a ratio $10^{150/20} > 30 \cdot 10^6$, but most instruments achieve 120–140 dB.

MEMS Accelerometers

The same principles described so far are valid regardless the size of the accelerometer, but accelerometer sensors of micrometric size have specific characteristics, so a brief description follows.

Originally, the aim of reducing the size of accelerometer sensors was due to the manufacturing of integrated accelerometers for industry and navigation (airborne) applications. The space exploration requirements, among other applications, led to the adaptation of some of the

techniques of manufacturing integrated circuits to the production of very lightweight and low-power-sensitive accelerometers.

In recent years, the industry has found a large number of consumer applications for this kind of accelerometers. This has led to the development of micro-sized, light and low-power sensors, suitable for mass production and thus inexpensive. These are the *micro-electro-mechanical system* (MEMS) devices. MEMS accelerometers are used for automotive industry (e.g., for air-bag triggering), inertial navigation, medical applications, game consoles, cellular phones, tablets and laptops, etc. Most of these devices have a poor performance for seismic recording, but a few commercial models are suitable for low-resolution strong ground motion recording and earthquake early warning (EEW) systems or for triggering shutoff procedures on critical facilities (trains, gas valves, lifts, critical machinery) in case of a strong earthquake (e.g., Yanada et al. 2002). Furthermore, some seismic instrumentation companies have developed MEMS accelerometers for seismic-grade recorders with comparable performance of conventional sensors. The idea is to build the mass-spring system within the multilayer structure of an integrated circuit (Fig. 9), using the same techniques as for electronic components and circuits.

The internal noise of a spring-mass system is due to the thermal-mechanical coupling by means of the damping dissipative forces. For instance, the air molecules interchange kinetic energy with the mass, which then “dances” randomly with a Brownian motion.

It may be shown (e.g., Aki and Richards 2002; Havskov and Alguacil 2010) that this noise is proportional (Eq. 14) to the mechanical damping coefficient h (not included the feedback effect) and inversely proportional to the suspended mass. The power spectral density (PSD) $\ddot{Z}_n^2$ of the mass acceleration noise (the PSD integrated between two frequencies gives the noise variance in this band) is

$$\ddot{Z}_n^2 = \frac{8k_B T}{m} h \omega_0 \quad (14)$$

Seismic Accelerometers, Fig. 9 Principal elements of a MEMS (micro-electro-mechanical system) accelerometer with capacitive transducer. The mass is the *upper* mobile capacitor plate which can rotate around the torsion bars. The displacement, proportional to acceleration, is sensed

with the variance in the capacitance. For high-sensitive applications, a feedback circuit is added which controls a restoring electrostatic force, thus making an FBA. The size of the sensor above is about 2 mm (Figure from www.silicondesigns.com/tech.html)

where k_B is the Boltzmann constant ($1.38 \cdot 10^{-23}$ J/K), T is Kelvin temperature, m the suspended mass, h the mechanical damping coefficient, and ω_0 the free angular frequency. This equation explains why a good part of the effort in improving MEMS accelerometer noise is focused (Walmsley et al. 2009) in increasing the proof mass and reducing damping.

Thus, for a micro mass, the open-loop damping should be kept as low as possible for an acceptable noise level at ambient temperature. High-purity silicon spring elements are almost perfectly elastic, and the spring is operating in vacuum to avoid air damping, so the mechanical damping can be held quite low.

Several strategies have been tested in prototypes for sensing the mass motion. Most commercial devices use some kind of variable capacitance. Other sensing designs are based on tunnel effect, optical diffraction and interferometry, piezo-resistivity, piezoelectricity, resonance, or electrochemical phenomena. Very small capacitive transducers are not practical in general, since the circuitry parasitic capacitances make the relative changes too small. Nevertheless, these parasitic capacitances may be reduced to a minimum in MEMS devices, since the associated circuit is integrated within the same chip (see, for instance, Li et al. 2001).

The two capacitive techniques described above are used: variable gap between plates and variable area. The first is quite nonlinear and usually requires electrostatic feedback to linearize the transducer response. Recently, electro-magnetic feedback has also been proposed for MEMS accelerometers (Dwyer 2011). On the other hand, the variable area technique is more linear, and some devices using it operate in open-loop mode (e.g., Homeijer et al. 2011). Figure 10 shows a possible arrangement for a MEMS accelerometer.

MEMS sensors are now made with electro-chemical sensors (Deng et al. 2013) with a noise PSD of $0.1 (\mu\text{m/s}^2)/\sqrt{\text{Hz}}$ or $10 \text{ ng}/\sqrt{\text{Hz}}$ at 1 Hz, so these sensors could be used at medium noisy sites.

All of these devices have two distinct parts within the same package: the mechanical sensor and the associated electronics, typically implemented by an ASIC (application-specific integrated circuit). Some commercial models have a sigma-delta modulator (a device yielding a sequence of logical pulses whose average value is proportional to its analog voltage input) included (see “► [Recording Seismic Signals](#)”), and so its output is a pulse-density digital signal, able to be directly interfaced to a microcontroller or computer. The integrated MEMS has to be

Seismic Accelerometers,

Fig. 10 A possible arrangement of the mass, spring, and capacitor plates in a MEMS accelerometer. All elements are in a layer a few microns thick

mounted in a printed circuit board (PCB) with some more electronics, at least a power supply unit, and optionally assembled in a casing with connectors, able to be fixed to another element. This assembly has to be rigid enough not to introduce parasitic resonances in the seismic band. Including electronics and housing, the total weight of these sensors might be around 0.1–0.5 kg. The sensor chip itself typically weighs less than 1 g.

The (US) Working Group on Instrumentation, Siting, Installation, and Site Metadata of the Advanced National Seismic System (ANSS 2008) defined four classes of strong-motion stations – A, B, C, and D – in terms of performance. Class A has the highest performance, with resolution better than $7\ \mu\text{g}$ and broadband dynamic range $> 111\ \text{dB}$ ($\geq 20\text{bit}$). Class B has a resolution between 7 and $107\ \mu\text{g}$ and a dynamic range 87–111 dB (or 16–20 bit). Class C resolution is $107\text{--}1,709\ \mu\text{g}$ and dynamic range 63–87 dB (12–16 bit). Class D has poorer performance than C. Currently (2014) there are no commercial MEMS accelerometers that fulfill the class A specifications, which are only met by classical macroscopic FBA devices. One of the reasons is the difficulty of achieving low noise levels with a so small suspended mass.

Several manufacturers use MEMSs for accelerograph recorders with class B performance, e.g., GeoSIG GMS-18 (www.geosig.com/productfile.html?productid=10319).

And some MEMS manufacturers offer class B accelerometers, e.g., Silicon Designs 1221 (www.silicondesigns.com/pdfs/1221.pdf) has typical noise PSD of $5\ \mu\text{g}/\sqrt{\text{Hz}}$ – an rms noise of $50\ \mu\text{g}$ over 100 Hz bandwidth. Recent designs (Homeijer et al. 2011) report noise levels under $100\ \text{ng}/\sqrt{\text{Hz}}$ or even $10\ \text{ng}/\sqrt{\text{Hz}}$ above 1 Hz (Milligan et al. 2011) with new capacitance transducers operating without feedback. These performances make it even suitable for use as exploration sensors, substituting geophones.

Class C devices are cheaper and mostly used in consumer products. Those models with stable response and enough bandwidth may be suitable to be applied in seismic strong ground motion monitoring, for instance, instrumental intensity estimation (shake maps), structural response, earthquake early warning, and shut off of critical facilities.

As an example of this class of sensors, Fig. 11 shows a MEMS triaxial accelerometer LIS 344 ALH (www.st.com/web/en/catalog/sense_power/FM89/SC444) from STMicroelectronics mounted on a small printed circuit board, which is sold as an evaluation board, since hand soldering the chip for prototyping is quite a difficult task. This chip accelerometer has a user-selectable full-scale $\pm 2\ \text{g}$ or $\pm 6\ \text{g}$ and comes with factory-trimmed sensitivity and offset. Its bandwidth may be selected by an external capacitor.

Seismic Accelerometers,
Fig. 12 *Upper*, accelerogram obtained with a class B accelerograph from an earthquake of moment magnitude $m_w = 3.8$ at an epicentral distance of 16 km. *Lower*, the simulated record with the MEMS sensor of Fig. 11 by adding the recorded self-noise

Figure 12 plots a small local earthquake recorded by a standard accelerometer and the simulated record with this sensor, using its real noise. The MEMS sensor shows a higher noise, but a useful signal is still available.

A comparative test of these sensors (Evans et al. 2014) shows that some of them could be very useful for low-cost seismic networks. Some models have performances suitable for strong ground motion recording with acceptable SNR to be used as class C seismic accelerometers.

Accelerometer Examples

Many seismic accelerometers commercially available are sold assembled with the corresponding

recorder in a case, which is called an accelerograph. Some of them may be acquired separately, with an analog voltage output for each axis. For earthquake recording, the standard is a triaxial instrument. Practically all the recorders have GPS synchronization of internal clock. Some models have the possibility of Internet timing, for sites where GPS signal cannot be received.

Most accelerograph manufacturers offer several models with different performance and price. The models shown below are just examples and may not be representative of the best instrument offered by each company.

Figure 13 shows one of the accelerometers with highest dynamic range, the EpiSensor from Kinemetrics (www.kinemetrics.com/p-87-EpiSensor-ES-T.aspx), a triaxial FBA with

Seismic Accelerometers, Fig. 13 The EpiSensor accelerometer from Kinemetrics. *Left*, surface sensor package. *Right*, the case is removed to show the components

Seismic Accelerometers, Fig. 14 The Etna accelerograph from Kinemetrics with its lid removed. It has an internal triaxial accelerometer (EpiSensor). The hermetic case is made of fiberglass

Seismic Accelerometers, Fig. 15 CMG 5TD from Guralp Systems. This model can include a recorder and an Ethernet interface. The photo shows a unit installed in an underground gallery with the mounting base anchored to the concrete ground

full-scale selectable up to ± 4 g. Also available is a uniaxial and with different packages, including borehole. It may be mounted inside a compact accelerograph package like Etna model (Fig. 14). This robust accelerograph model has been in the market for many years, so, in spite of the good accelerometer inside, its performance as recorder (dynamic range, communication interface, data storage) does not fully match the sensor specifications, and it may be considered a class B accelerograph. The same manufacturer offers new recorder models with higher performance.

Guralp Systems (www.guralp.com/products/instruments/cm-g-5) CMG5 (Fig. 15) is an FBA

with high dynamic range that can be supplied with built-in digitizer, recorder, and communication facilities. It is a class A accelerograph. A borehole version is also available.

Figure 16 shows Nanometrics Titan (www.nanometrics.ca/products/titansma). It is one of the newest class A accelerographs, with internal FBA and high dynamic range in a very compact

Seismic Accelerometers, Fig. 16 Nanometrics Titan accelerograph. Its size is approximately 18 x 12 x 10 cm

Seismic Accelerometers, Fig. 18 The REFTEK 148-1 “QuakeRock” accelerograph, with MEMS sensor (Photo from REFTEK (www.reftek.com/products/motion-recorders-148-01.htm))

Seismic Accelerometers, Fig. 17 FBA with MEMS technology AC-43 from GeoSIG. It weighs 2 kg and its size is 19 x 11 x 9 cm (Figure from GeoSIG (www.geosig.com/AC-4x-id10357.html))

package. It has a web interface and can store data in a removable SD memory card.

Finally, two accelerometers with MEMS technology will be shown. In Fig. 17, the GeoSIG AC-43 (www.geosig.com/AC-4x-id10357.html) is a triaxial FBA with class B performance when mounted inside or connected to a recorder, such as the GSR-18, from the same company. The model 148-01 “QuakeRock” from REFTEK (Fig. 18)

is a class C accelerograph with only event recording (not continuous) and limited dynamic range but may operate unattended for 2 years with two “D” size batteries. The internal clock is free running (no GPS).

Accelerograph Installation

Two kinds of accelerometer or accelerograph installations are possible: (a) free-field installation and (b) structural-monitoring installation. The purpose of the first is to record the ground motion unaffected by man-made structures. The acceleration records obtained from this kind of stations may be considered the base-level excitation of any building or structure in the zone, if the building itself does not interact with the ground at the station. The second type is an accelerograph in a building or engineering structure at different levels and positions to study and monitor the structure vibrations in response to ground seismic motions.

The main consideration is that the installation setup should not affect the accelerograph records.

For free-field stations, it is usual to build a small concrete pier on which the accelerometer (or accelerograph if the sensor is inside it) must be firmly anchored so a strong motion cannot move the instrument relative to ground! Most commercial instruments include a suitable base with anchoring holes or a similar system. Other materials for pier, like a table made with steel bars, are not suitable since it may resonate with very low damping in the seismic band of interest.

Free-field accelerographs should not be close to tall buildings that may modify the ground motion in their proximity. Actually some accelerograph stations are installed at the basement of buildings and are considered as free-field but may not truly fulfill this condition, due to the soil-structure interaction.

If the free-field installation is to be done on soil, the pier should have a suitable foundation to assure that it is well coupled to the ground, but not being so heavy as to modify the local soil dynamic response substantially. Free-field accelerographs must be protected with a cover or small hut from the weather. Provisions have to be made for power supply, GPS antenna, and communication, usually Ethernet via cable, satellite link, or cellular modem. And a fence around the installation would protect it from animals, human-made noises, and eventually vandalism. Accelerographs are not very sensitive to weak motions, but modern high-resolution instruments are capable of detecting human activity such as traffic or machinery working at short distance, so this kind of noise should be avoided as far as possible.

Structural-monitoring installations are usually done under cover, and additional weather protection is not required, but the instrument may have to be protected from human activity or other disturbances. Normally a pier is not required, since the sensor may be anchored directly to a structural element. GPS reception for time synchronism may be a problem if the station is far from the open sky (e.g., in a dam gallery), but there exist technical solutions: e.g., a GPS receiver may be outside, and the signal is “repeated”; the accelerograph may be

synchronized via Ethernet or the accelerometer is installed on the site, and the recorder is separately installed near the open sky so the GPS antenna can be placed outside.

Summary

Seismic accelerometers sense the ground or structure seismic vibrations and, together with a suitable recorder, are called accelerographs. Most modern seismic accelerometers are of force-balance type (FBA), a servo system in which a feedback force is applied to the suspended inertial mass to keep its motion as small as possible. This improves the instrument linearity and dynamic range. Usually the mass motion is measured by a sensitive capacitive transducer.

MEMS accelerometers are integrated micromachined electromechanical devices widely used in industry that presently do not match the classical FBA performance, but are useful for some seismic applications.

Examples of commercial seismic accelerometers and accelerographs and some brief guidelines for the installation of free-field and structure-monitoring accelerographs are given.

Introduction

Near-fault seismic ground motions are frequently characterized by intense velocity and displacement pulses of relatively long duration that clearly distinguish them from typical far-field ground motion records. This observation, along with its engineering significance, was first made with respect to the C02 record (Fig. 1a) generated by the 1966 Parkfield earthquake at a distance of only 80 m from the fault break (Housner and Trifunac 1967). The damage that the Olive View Hospital sustained during the 1971 San Fernando earthquake was also attributed to the effect of near-fault ground motions on flexible structures (Bertero et al. 1978). That was perhaps the first time that earthquake engineers linked the structural damage caused by an earthquake to the impulsive character of near-fault ground motions (Fig. 1b). However, it was not until the 1994 Northridge and the 1995 Kobe earthquakes that the majority of engineers recognized the destructive potential of near-fault ground motions and started considering methods to incorporate near-source effects into engineering design. Code provisions have historically been developed based on recorded ground motions not sufficiently close to the causative fault. Thus, the effect of near-fault pulse-like ground motions on the dynamic

response of engineering structures has received much attention over the past two decades.

This entry focuses on the description of seismic actions due to near-fault ground motions with particular emphasis on the following topics: (1) characteristics of near-fault ground motions, (2) effect of fault rupture parameters on near-fault seismic excitations, (3) synthesis of near-fault ground motion time histories for earthquake engineering applications, and (4) derivation of response spectra, strength reduction factors and

damping coefficients for engineering analysis and design in the near-fault region. The material presented in this entry is primarily based on previous articles published by the author and Professor Apostolos S. Papageorgiou and is presented in a manner that provides established knowledge in the disciplines of engineering seismology and earthquake engineering to technically inclined and informed readers. It should be emphasized that this entry does not intend to be a specialized research article advancing the current state of

knowledge or a review article summarizing the vast amount of archived research literature on the subject.

Characteristics of Near-Fault Ground Motions

Not all ground motion time histories recorded at stations in the vicinity of a fault exhibit intense velocity pulses. The existence of pulse-like ground motions in near-fault records primarily depends on the relative position of the station that recorded the motion with respect to the direction of propagation of rupture on the causative fault plane and on the magnitude and direction of slip on that segment of the fault that is located in the vicinity of the station. Whenever these ground motion pulses do occur, they are typically caused by the forward directivity and/or permanent translation (fling) effects.

Forward directivity occurs when the fault rupture propagates toward a site with a rupture velocity that is approximately equal to the shear wave velocity. In this case, most of the energy arrives coherently in a single, intense, relatively long-period pulse at the beginning of the record representing the cumulative effect of almost all the seismic radiation from the fault. Forward directivity pulses are polarized in the fault-normal direction for both strike-slip and dip-slip

faults. Figure 2 illustrates a characteristic example of forward directivity from the 1992 Landers earthquake. The fault rupture propagated to the north along the indicated strike-slip fault. The fault-normal velocity and displacement time histories recorded at Lucerne Valley (LUC) station (which is located in the forward direction with respect to the propagation of rupture) are characterized by intense pulse-like motions. In contrast, the ground motion recorded at Joshua Tree (JSH) station (which is located in the backward direction with respect to the propagation of rupture) is relatively weak.

Permanent translation (fling) is a consequence of permanent fault displacement due to an earthquake; it appears in the form of step displacement and one-sided velocity pulse in the strike-parallel direction for strike-slip faults or in the strike-normal direction for dip-slip faults. In the latter case, directivity and permanent translation effects “build up” in the same direction. Figure 3 illustrates characteristic examples of permanent translation (fling) from the 1999 Izmit earthquake. The fault-parallel velocity and displacement time histories recorded at Yarimca (YPT) and Sakarya (SKR) stations are affected by the permanent displacement along the right-lateral strike-slip North Anatolian Fault.

Even though emphasis has traditionally been given to the investigation of forward directivity and permanent translation (fling) effects, other

Seismic Actions Due to Near-Fault Ground Motion, Fig. 3 Characteristic examples of permanent translation (fling) from the 1999 Izmit, Turkey, earthquake

conditions may also give rise to near-fault pulse-like motions. A comprehensive review of the factors that influence near-fault ground motions, along with a detailed list of references on the subject, has been presented by Mavroeidis and Papageorgiou (2002, 2003). Figure 4 illustrates a large number of actual near-fault ground motion records with “distinct” velocity pulses. These records are part of the near-fault ground motion database compiled by Mavroeidis and Papageorgiou (2003). It is evident that the pulse duration (or period), the pulse amplitude, as well as the number and phase of half cycles are the key parameters that define the waveform characteristics of the near-fault velocity pulses.

Effect of Fault Rupture Parameters on Near-Fault Ground Motions

The effect of fault rupture characteristics on near-fault ground excitations has been investigated by Mavroeidis and Papageorgiou (2010) using a kinematic modeling approach. In order to associate fault rupture characteristics (such as slip, rupture velocity, and state of stress) with near-fault ground motions, four well-documented seismic events (1979 Imperial Valley, 1985 Michoacan, 1989 Loma Prieta, and 1999 Izmit) were considered along with the concept of isochrones. An isochrone is the locus of all those points on the fault plane, the radiation of which arrives at a certain observer at a specified time.

Isochrones are frequently used in seismology to provide intuitive insight into factors that strongly influence the generation of strong ground motions. By plotting the *S*-wave isochrones on the fault plane of the investigated seismic events, the long-period velocity pulses of the near-fault ground motions can be directly associated with specific regions and characteristics of the fault rupture.

The results indicated that the seismic energy radiated from the high-isochrone-velocity region of the fault arrives at the receiver within a time interval that coincides with the time window of the long-period ground motion pulse recorded at the site. Furthermore, the near-fault ground motion pulses are strongly correlated with large slip on the fault plane locally driven by high stress drop. In addition, the local rupture velocity seems to be inversely correlated to the spatial distribution of the strength excess over the fault plane confirming findings of previous studies (e.g., Bouchon 1997). As an example, Fig. 5 illustrates time histories of near-fault ground motions and *S*-wave isochrones for selected stations of the 1979 Imperial Valley earthquake. These stations are located close to the ruptured fault where the effect of forward directivity was pronounced. The spatial distribution of the static slip offset and rupture time inferred by Archuleta (1984) and the spatial distribution of the static stress drop and strength excess calculated using the methodology proposed by Bouchon (1997) are also illustrated.

Seismic Actions Due to Near-Fault Ground Motion, Fig. 4 Strong motion records with “distinct” velocity pulses (Reprinted from Mavroeidis and Papageorgiou (2003). Copyright © 2003 Seismological Society of America)

Finally, it was found that for various events, the area of the fault that contributes to the formation of the near-fault pulse encompasses more than one patch of significant moment release (subevent) (e.g., 1979 Imperial Valley, 1989 Loma Prieta). This observation explains why a dislocation model with average properties (i.e., slip, rise time, etc.) reproduces successfully near-fault ground motions for strike-slip faults and for dip-slip faults with intermediate-to-large earthquake magnitudes. However, for very large earthquakes, such as megathrust events on subduction zones (e.g., 1985 Michoacan), the fault region that contributes to the pulse formation

encompasses individual subevents, and, consequently, crack-like slip functions (rather than dislocation models) may be more appropriate for the simulation of the near-fault ground motions. The interested reader may find a detailed discussion in Mavroeidis and Papageorgiou (2010).

Time Histories of Near-Fault Ground Motions

The advent of performance-based earthquake engineering, the growth of computer processing power, and the associated increased availability

Seismic Actions Due to Near-Fault Ground Motion, Fig. 5 Recorded (*black trace*) and synthetic (*gray trace*) near-fault ground motion time histories and *S*-wave isochrones for selected stations of the 1979 Imperial Valley, California, earthquake. Tomographic images of the static

slip offset, rupture time, static stress drop, and strength excess are also illustrated (Reprinted from Mavroeidis and Papageorgiou (2010). Copyright © 2010 Seismological Society of America)

of structural analysis software have made possible the performance of sophisticated nonlinear structural analysis on a routine basis. However, the overall seismic performance-based assessment of a given structure hinges on the use of realistic earthquake ground motions that reflect the seismic hazard at the site of the structure, as well as the local site conditions (Halldorsson et al. 2011).

In general, earthquake engineers have the following options for selecting ground motion input when performing nonlinear structural analysis in the near-fault region: (1) use actual records of near-fault ground motion, (2) generate synthetic records of near-fault ground motion using physical models of the seismic source, and (3) generate synthetic records of near-fault ground motion using phenomenological models.

Recorded Near-Fault Ground Motions

The gradually increasing number of recorded near-fault ground motions has recently enabled strong motion seismologists to compile these records in publicly available ground motion databases (e.g., Pacific Earthquake Engineering Research Center Ground Motion Database, Center for Engineering Strong Motion Data, European Strong Motion Database, among others). Even though the number of near-fault records is still limited, they have served as an invaluable resource to earthquake engineers. Researchers have also proposed methodologies for identifying and extracting pulse-like motions from actual near-fault records using wavelet analysis (e.g., Baker 2007; Vassiliou and Makris 2011).

However, the selection of strong motion records for nonlinear structural analysis is not always a straightforward process. For instance, the available records may not reflect the appropriate earthquake magnitude, source mechanism, site conditions, or source-site configuration. While this could be a problem for far-field sites, it is even a greater challenge for sites in the immediate vicinity of the fault. For the above reasons, it is of paramount importance to earthquake engineers to have the ability to generate suites of realistic broadband ground motion time

histories, both in the far-field and near-fault regions (Halldorsson et al. 2011).

Synthetic Near-Fault Ground Motions Using Physical Models of the Seismic Source

Strong motion seismologists have utilized various schemes of deterministic and stochastic simulation techniques to generate broadband ground motion time histories at specific locations in the vicinity of the fault (see, e.g., Papageorgiou 1997 and references provided therein). These simulation methods are based on source mechanics principles and wave propagation theory. Site effects are also frequently taken into account. Regardless of the degree of sophistication of the various ground motion simulation methods, the Earth crustal structure and the seismic source should sufficiently be characterized and quantified.

For regions of intense seismic activity, the crustal structure is frequently defined in terms of one-dimensional velocity models. Detailed three-dimensional crustal models have also become available for specific regions in the benefit of three-dimensional wave propagation codes that may effectively take into account basin effects and complex fault geometries at the cost of increased computational demands. The characterization of the seismic source is a more complicated issue. For kinematic descriptions of the earthquake source, source parameters such as slip, rise time, rupture velocity, and slip function should properly be quantified and a priori defined. On the other hand, for dynamic descriptions of the earthquake source, the source parameters may vary as long as the elastodynamics equation with a prescribed fracture criterion on a predetermined fault plane is satisfied. The selected initial conditions and failure criterion determine the time and space evolution of the fault rupture in a dynamic source model.

Once the seismic source and Earth crustal model have been adequately described, near-fault ground motion simulations in the low-frequency range (e.g., below 1 Hz) can be performed using deterministic modeling techniques [e.g., discrete wavenumber method (DWN), finite difference method (FDM), finite element method (FEM), boundary element

method (BEM), spectral element method (SEM), or hybrids of them] that involve calculations of synthetic Green's functions. In order to generate broadband synthetic ground motions, the low-frequency waveforms should be combined with high-frequency ground motions (e.g., above 1 Hz) simulated using: (1) the empirical or semiempirical Green's function method or (2) a stochastic modeling technique utilizing a source model that provides an unambiguous way to distribute the seismic moment of the simulated event on the fault plane. This matter is of great importance for near-fault ground motion simulations due to the proximity of the point of observation to the source. It should be mentioned that high-frequency ground motion simulations can be carried out using synthetic Green's functions as well, excluding site effects and small-scale heterogeneities.

Synthetic Near-Fault Ground Motions Using Phenomenological Models

Ground motion simulation techniques based on kinematic or dynamic source models are not always appealing to earthquake engineers because specialized seismological knowledge and, quite frequently, demanding computational resources are required. Therefore, in practice, earthquake engineers utilize actual near-fault records of past earthquakes to investigate the dynamic response of engineering structures to pulse-like seismic excitations and rely on strong motion seismologists only for generating site-specific near-fault ground motions for the design of special structures.

To overcome this deficiency, earthquake engineers have introduced idealized waveforms, intending to represent typical ground motion pulses observed in the near-fault region, in an effort to investigate the dynamic response of engineering structures to near-fault ground motions (e.g., Makris 1997; Sasani and Bertero 2000; Alavi and Krawinkler 2001; Mavroeidis and Papageorgiou 2003, among others). These idealized waveforms should successfully capture the impulsive character of the near-fault records both qualitatively and quantitatively. In addition, their input parameters should have a clear physical

interpretation and scale, to the extent possible, with physical parameters of the faulting process.

Mathematical Representation of Near-Fault Ground Motion Pulses Proposed by Mavroeidis and Papageorgiou (2003)

The mathematical formulation for the representation of the near-fault ground velocity pulses proposed by Mavroeidis and Papageorgiou (2003) is the product of a harmonic oscillation with a bell-shaped function. That is:

$$v(t) = \begin{cases} A \frac{1}{2} \left[1 + \cos \left(\frac{2\pi f_p}{\gamma} (t - t_0) \right) \right] \cos [2\pi f_p (t - t_0) + v], \\ t_0 - \frac{\gamma}{2f_p} \leq t \leq t_0 + \frac{\gamma}{2f_p} \text{ with } \gamma > 0, \text{ otherwise} \end{cases} \quad (1)$$

where A controls the amplitude of the signal, f_p is the frequency of the amplitude-modulated harmonic (or the prevailing frequency of the signal), v is the phase of the amplitude-modulated harmonic, γ is a parameter that defines the oscillatory character of the signal, and t_0 specifies the epoch of the envelope's peak. The pulse period (T_p) is defined as the inverse of the prevailing frequency (f_p) of the signal, thus providing an "objective" assessment of this important parameter. That is:

$$T_p = \frac{1}{f_p} \quad (2)$$

The model input parameters have a clear physical meaning as they coincide with the key features that determine the waveform characteristics of the near-fault pulses (i.e., amplitude, duration, phase and number of half cycles).

The mathematical model proposed by Mavroeidis and Papageorgiou (2003) was calibrated using a large number of actual near-fault records. It successfully replicated a large set of displacement, velocity, and, in many cases, acceleration time histories, as well as the corresponding elastic response spectra. A sample of the quality of fitting of the synthetic waveforms to actual near-fault records is illustrated in Fig. 6.

The scaling characteristics of the model input parameters were also investigated through

Seismic Actions Due to Near-Fault Ground Motion, Fig. 6 Sample of synthetic waveforms (*black trace*) fitted to actual near-fault records (*gray trace*). Ground motion time histories (displacement, velocity, and acceleration),

as well as the 5% damped elastic response spectra are illustrated (Reprinted from Mavroeidis et al. (2004). Copyright © 2004 John Wiley & Sons, Inc.)

regression analysis, and simple empirical relationships were proposed. By performing least-squares analysis (Fig. 7a), the following relationship was obtained between the pulse period and the earthquake magnitude:

$$\log T_P = -2.2 + 0.4 M_w \quad (3a)$$

If the empirical relationship is required to satisfy the self-similarity condition, the following equation can be obtained:

$$\log T_P = -2.9 + 0.5 M_w \quad (3b)$$

Equation (3) was derived by Mavroeidis and Papageorgiou (2003) using near-fault ground

motion records affected by forward directivity. Similar scaling equations have been proposed by other investigators (e.g., Somerville 2003; Bray and Rodriguez-Marek 2004; Baker 2007, among others). However, it should be pointed out that the definition of the pulse period in these studies is not the same as the definition provided by Mavroeidis and Papageorgiou (2003), and therefore caution should be utilized when the mathematical model of Eq. 1 is used in conjunction with scaling laws for the pulse period proposed by other investigators.

Mavroeidis et al. (2004) also derived an equation that relates the pulse period (T_P) with the rise time (τ) (i.e., the time it takes for a representative point on the fault plane to reach its final displacement). The rise time is an important physical

Seismic Actions Due to Near-Fault Ground Motion, Fig. 7 (a) Scaling of the pulse period with earthquake magnitude, according to Mavroeidis and Papageorgiou (2003), and (b) attenuation of peak ground velocity with

rupture distance, according to Halldorsson et al. (2011) (Reprinted from Halldorsson et al. (2011). Copyright © 2011 American Society of Civil Engineers)

parameter of the fault rupture process that greatly affects strong ground motion characteristics. In fact, the rise time (and therefore the pulse period) is related to one of the characteristic corner frequencies of the source spectrum (i.e., the spectrum of seismic waves radiated by the earthquake source before these are modified by propagation path and site effects).

On the other hand, the peak value of the near-fault velocity records appears to be a fairly stable parameter. A value of 100 cm/s effectively represents peak ground velocities within a few kilometers from the causative fault regardless of the earthquake magnitude (Mavroeidis and Papageorgiou 2003). This observation is in good agreement with the typical slip velocity value of 100 cm/s frequently considered by seismologists. As indicated by Mavroeidis et al. (2004), there are solid physical reasons that explain the stability of the velocity amplitude close to the fault. More recently, Halldorsson et al. (2011) proposed the following attenuation relationship for peak ground velocity (PGV) with rupture distance (R) (Fig. 7b):

$$\log PGV = 2.040 - 0.032 R \quad (4)$$

Once PGV has been determined using Eq. 4, parameter A that controls the amplitude of the

synthetic velocity pulse can be defined by considering that $A \sim (0.85-1.00)$ PGV. Other investigators have also proposed attenuation relationships for PGV (e.g., Bray and Rodriguez-Marek 2004, among others).

Finally, parameter γ varies from a value slightly larger than 1 up to a maximum value of 3, while the phase angle (ν) varies from 0° to 360° . Halldorsson et al. (2011) have provided the probability density functions of γ and ν , assuming that these two parameters are normally distributed.

Simplified Methodology for Generating Broadband Near-Fault Ground Motions Proposed by Mavroeidis and Papageorgiou (2003)

As explained by Mavroeidis and Papageorgiou (2003), the mathematical expression of Eq. 1 replicates accurately the intermediate-to-long-period (“coherent”) features of the near-fault ground motions. The high-frequency components that are “incoherent” cannot be simulated using simplified mathematical models (see, e.g., acceleration time histories and the short-period range of response spectra in Fig. 6).

A simplified methodology for generating realistic, broadband, near-fault ground motions that are adequate for engineering analysis and design was proposed by Mavroeidis and Papageorgiou (2003).

Based on this technique, the coherent (long-period) ground motion component is simulated using the mathematical model of Eq. 1, while the incoherent (high-frequency) seismic radiation is synthesized using the specific barrier model (Papageorgiou and Aki 1983a, b) in the context of the stochastic modeling approach. The specific barrier model is a physical model of the seismic source that applies both to the “near-fault” and “far-field” regions, allowing for consistent ground motion simulations over the entire frequency range and for all distances of engineering interest. The specific barrier model has been calibrated to shallow crustal earthquakes of three different tectonic regions: interplate, intra-plate, and extensional regimes (Halldorsson and Papageorgiou 2005).

This simplified methodology has been applied to hypothetical and actual earthquakes (e.g., Mavroeidis and Papageorgiou 2003; Halldorsson et al. 2011) and is demonstrated in this entry through the case study of the 1971 San Fernando earthquake (Mavroeidis 2004). According to Heaton (1982), the 1971 San Fernando earthquake with M_W 6.6 may have been a double seismic event that occurred on two subparallel thrust faults, the Sierra Madre and San Fernando Faults, as indicated in Fig. 8a. The slip distribution on the causative faults, inferred by inversion of teleseismic, strong motion, and geodetic data, is illustrated in Fig. 8b. The damage that the Olive View Hospital sustained during the earthquake has been attributed to the destructive potential of near-fault ground motions on flexible structures (Bertero et al. 1978). No strong motion instruments were installed in the immediate vicinity of the hospital building. However, there are indications that the ground motion that the Olive View Hospital sustained was equivalent or greater than the ground motion recorded at the nearby Pacoima Dam (PCD) station.

Broadband synthetic time histories are generated at the location of the Olive View Hospital for the fault-station geometry of Fig. 8a. The mathematical model of Eq. 1 is first employed to generate the coherent component of the ground motion at the Olive View Hospital. The values for the input parameters A , f_p , γ , and ν are those inferred by fitting the mathematical model of

Eq. 1 to the ground motion time histories and response spectra of the PCD record (see Mavroeidis and Papageorgiou 2003). For the synthesis of the incoherent seismic radiation at the location of the Olive View Hospital, the specific barrier model of Papageorgiou and Aki (1983a) is utilized. The selected parameters for the specific barrier model are consistent with the values inferred by Papageorgiou and Aki (1983b) for the 1971 San Fernando earthquake. The model consists of two subevents (Fig. 8c), in agreement with the two distinct slip patches of similar size inferred for this event by Heaton (1982) (Fig. 8b). The site characterization at the Olive View Hospital is assumed to be NEHRP site class D consistent with available information.

Figure 9a illustrates the synthetic ground motions (strike-normal component) at the Olive View Hospital. The top and middle panels display the incoherent and coherent ground motion components, while the bottom panels show the superposition of the above two components. For comparison purposes, the ground motion recorded at the nearby PCD station due to the 1971 San Fernando earthquake is also shown in Fig. 9b. The overall agreement between the synthetic ground motions at the Olive View Hospital and the recorded ground motions at PCD station is very good. It is evident that acceleration amplitudes larger than those recorded at the PCD station characterize the synthetic accelerogram at the Olive View Hospital. On the other hand, the corresponding velocity and displacement time histories are very similar. These differences in acceleration amplitudes may be attributed to the different site conditions at the locations of the Olive View Hospital (NEHRP site class D) and Pacoima Dam (NEHRP site class B; rock good enough to serve as the foundation of a concrete dam).

Response Spectra, Strength Reduction Factors, and Damping Coefficients for Near-Fault Ground Motions

In this section, the primary characteristics of near-fault ground motion response spectra are discussed, and recommendations are made for

Seismic Actions Due to Near-Fault Ground Motion, Fig. 8 (a) Cross-sectional view of the causative faults of the 1971 San Fernando, California, earthquake (Heaton 1982), (b) slip distribution in meters for the two

subparallel thrust faults of Fig. 8a (Heaton 1982), and (c) subevents of the specific barrier model represented by two circular cracks (ω^2 -model) (Reprinted from Mavroeidis (2004). Copyright © 2004 G. P. Mavroeidis)

Seismic Actions Due to Near-Fault Ground Motion, Fig. 9 (a) Synthesis of near-fault ground motions at the location of the Olive View Hospital for the fault-station geometry illustrated in Fig. 8a; the 5% damped elastic

response spectra are also shown. (b) Actual ground motions recorded at the nearby Pacoima Dam (PCD) station (Reprinted from Mavroeidis (2004). Copyright © 2004 G. P. Mavroeidis)

design spectra, strength reduction factors and damping coefficients for analysis, and design in the near-fault region. The interested reader may find additional information in Mavroeidis et al. (2004) and Hubbard and Mavroeidis (2011).

Response Spectra

Figure 10a displays the 5% damped equal-ductility pseudo-velocity response spectra of elastic-perfectly plastic single-degree-of-freedom (SDOF) systems subjected to a large

Seismic Actions Due to Near-Fault Ground Motion, Fig. 10 Standard and normalized 5% damped equal-ductility ($\mu = 1.0, 4.0, 8.0$) pseudo-velocity response spectra of elastic-perfectly plastic SDOF systems

subjected to actual near-fault ground motion records: (a) PSV versus T_n , (b) PSV versus T_n/T_P , and (c) PSV/A versus T_n/T_P (Reprinted from Mavroeidis et al. (2004). Copyright © 2004 John Wiley & Sons, Inc.)

number of actual near-fault ground motion records (Mavroeidis et al. 2004). Inspection of this figure reveals that peak spectral amplitudes of near-fault records vary significantly, especially for smaller values of the ductility factor (μ). Furthermore, the periods that correspond to peak spectral amplitudes are characterized by significant dispersion.

Figure 10b illustrates the equal-ductility pseudo-velocity response spectra of Fig. 10a with the period axis normalized with respect to the corresponding T_P values estimated by

Mavroeidis and Papageorgiou (2003). This abscissa normalization yields response spectra characterized by peak spectral amplitudes that lie within a very narrow range of the normalized period (i.e., $T_{\text{peak}}/T_P \approx 0.7\text{--}1.0$ for elastic spectra). If the ordinates of the equal-ductility pseudo-velocity response spectra are further normalized with respect to A , the normalized response spectra of Fig. 10c are obtained; these spectra are characterized by small dispersion of normalized peak spectral amplitudes. In addition, they exhibit smaller dispersion in the normalized

Seismic Actions Due to Near-Fault Ground Motion, Fig. 11 Normalized 5% damped equal-ductility pseudo-velocity response spectra of elastic-perfectly plastic SDOF systems: (a) all earthquakes (M_W 5.6–7.6), (b) moderate earthquakes (M_W 5.6–6.3), (c) moderate-to-large earthquakes (M_W 6.4–6.7), and (d) large earthquakes

(M_W 6.8–7.6). The solid and dashed lines represent the mean and mean-plus-one-standard-deviation pseudo-velocity response spectra, respectively. The gray region represents the range of variation of the spectral amplitudes (Reprinted from Mavroeidis et al. (2004). Copyright © 2004 John Wiley & Sons, Inc.)

long-period range and larger dispersion in the normalized high-frequency range (controlled by the coherent and incoherent ground motion components, respectively).

Thus, it may be concluded that parameters A and T_P can be used to normalize the response spectra of actual near-fault records. This development facilitates the systematic investigation of the response spectrum characteristics of the SDOF system subjected to near-fault ground motions. It should be noted that the normalization of the ordinates of the equal-ductility pseudo-velocity response spectra of Fig. 10a with respect to PGV values yields normalized response spectra very similar to those illustrated in Fig. 10c. This is anticipated because parameter A effectively approximates PGV.

In order to investigate the effect of the earthquake magnitude on the normalized response spectra of Fig. 11a, the seismic events have been grouped into three categories: moderate (M_W 5.6–6.3), moderate-to-large (M_W 6.4–6.7), and large (M_W 6.8–7.6) earthquakes. The normalized equal-ductility pseudo-velocity response spectra of these three categories are displayed in Fig. 11b, c, d, respectively. It becomes evident that, for smaller values of T_n/T_P , the normalized spectral amplitudes increase with earthquake magnitude. However, for larger T_n/T_P values, the normalized response spectra appear to exhibit a uniform behavior regardless of the variation in earthquake magnitude. As a consequence, the normalized response spectra of large earthquakes exhibit flatter shapes around their peaks than the

Seismic Actions Due to Near-Fault Ground Motion, Fig. 12 Schematic illustrations of idealized response spectra in four-way logarithmic plots for far-field and

normalized response spectra of moderate earthquakes.

The ensemble of the normalized elastic response spectra illustrated in the first panel of Fig. 11 can be utilized to derive normalized elastic design spectra for moderate, moderate-to-large, and large earthquakes, as well as for the entire set of seismic events considered by Mavroeidis et al. (2004). The solid and dashed lines in the top panel of Fig. 11 represent the mean and mean-plus-one-standard-deviation 5% damped normalized elastic response spectra. These average elastic response spectra can be used to derive normalized elastic design spectra for two different nonexceedance probability levels.

Figure 12a displays a sketch of the standard idealized elastic design spectrum derived from far-field ground motion records. This standard design spectrum has been used for many decades since it was first introduced in engineering practice. The acceleration-, velocity-, and displacement-sensitive regions of this design spectrum can readily be identified in Fig. 12a. On the other hand, the normalized response spectra of the near-fault ground motion records (see Fig. 11) can be approximated by the sequence of linear segments displayed in Fig. 12b. The values of the characteristic normalized periods

near-fault ground motion records (Reprinted from Mavroeidis et al. (2004). Copyright © 2004 John Wiley & Sons, Inc.)

$[(T_n/T_P)_a, (T_n/T_P)_b, (T_n/T_P)_c, (T_n/T_P)_d, \text{ and } (T_n/T_P)_f]$ are provided in Mavroeidis et al. (2004).

Strength Reduction Factors

The earliest and perhaps the simplest recommendation of a procedure to construct inelastic spectra from elastic spectra using ductility-dependent strength reduction factors (R_y) is based on the work of Veletsos and Newmark (1960). These results were further developed by Newmark and Hall (1982) based on a suite of far-field ground motion records. Mavroeidis et al. (2004) checked the validity of the reduction factors proposed by Newmark and Hall (1982) for the response spectra of near-fault ground motion records by normalizing the period intervals of the R_y design equations as follows:

$$R_y = \begin{cases} 1, & \frac{T_n}{T_P} < \left(\frac{T_n}{T_P}\right)_a \\ \sqrt{2\mu-1}, & \left(\frac{T_n}{T_P}\right)_b < \frac{T_n}{T_P} < \left(\frac{T_n}{T_P}\right)_{c'} \\ \mu, & \frac{T_n}{T_P} > \left(\frac{T_n}{T_P}\right)_c \end{cases} \quad (5)$$

where $\left(\frac{T_n}{T_P}\right)_{c'} = \frac{\sqrt{2\mu-1}}{\mu} \left(\frac{T_n}{T_P}\right)_c$. The characteristic values of $(T_n/T_P)_a$, $(T_n/T_P)_b$, and $(T_n/T_P)_c$ are

associated with the normalized elastic design spectrum for near-fault ground motions (see Fig. 12b) proposed by Mavroeidis et al. (2004).

Figure 13 compares the computed values of R_y from the mean elastic and inelastic 5% damped normalized response spectra of Fig. 11 with the R_y values obtained from Eq. 5. The agreement between the two sets of curves is very good over the entire period range, for all specified ductility factors, and for all earthquake magnitude categories. Figure 13 demonstrates that the Veletsos-Newmark-Hall design equations can be used for near-fault ground motions as well, provided that normalized response spectra are utilized and appropriate values of $(T_n/T_P)_a$, $(T_n/T_P)_b$, and $(T_n/T_P)_c$ are selected.

Damping Coefficients

Damping coefficients are frequently used in earthquake engineering as a simple way to adjust the pseudo-acceleration or displacement response spectra associated with a viscous damping ratio of 5% to the higher values of viscous damping needed for design of structures equipped with base isolation and/or supplemental energy dissipation devices. Damping coefficients are also frequently used for predicting the maximum displacement demands of an inelastic structure from the maximum displacement demands of its equivalent linear system characterized by a longer natural period and a higher viscous damping ratio.

Damping coefficients (B) are defined as $B(T, \beta) = PSA(T, \beta = 5\%) / PSA(T, \beta)$, where T is the elastic period of vibration of the structure, β is the viscous damping ratio, and PSA are the ordinates of the pseudo-acceleration response spectra for particular values of T and β . Damping coefficients (B) are also known as “damping adjustment factors.” The reciprocal of B is often used in the literature and referred to as “damping correction factor,” “damping reduction factor,” “spectral scaling factor,” or “damping modification factor.”

Hubbard and Mavroeidis (2011) calculated damping coefficients for the SDOF system subjected to near-fault pulse-like ground motions for a large range of periods and damping levels.

The results indicated that damping coefficients proposed in design codes and previous studies, based primarily on far-field ground motion records, tend to not be conservative for near-fault pulse-like seismic excitations. Figure 14a illustrates the relationships between damping coefficient and period that were established for viscous damping ratios in the range of 5–100%. These damping coefficient curves were generated using the definition of B factors and the median pseudo-acceleration response spectra for various levels of damping.

In order to investigate the effect of earthquake magnitude on damping coefficients using near-fault records, the seismic events were again grouped into three categories labeled as moderate (M_W 5.6–6.3), moderate-to-large (M_W 6.4–6.7), and large (M_W 6.8–7.6) earthquakes. The variation of damping coefficient with period for these three categories is displayed in Figs. 14b, c, d for viscous damping ratios in the range of 5–100%. While the B factors for all three earthquake magnitude categories attain approximately the same peak values for a given damping ratio, the period range over which these peak values occur clearly depends on earthquake magnitude. In addition, the damping coefficient curves of Fig. 14a derived from the entire ground motion ensemble smooth out the effect of earthquake magnitude and therefore do not capture the particular features of the damping coefficient plots illustrated in Figs. 14b, c, d.

Figure 15 indicates that the normalization of the period axis of the B plots with respect to T_P yields damping coefficient curves that show a much stronger resemblance to each other. More specifically, the normalized damping coefficient curves for all groups of records attain comparable peak values for a given damping ratio. These maximum values tend to be slightly closer than the peaks observed on the non-normalized damping coefficient curves displayed in Fig. 14. In addition, the normalized periods over which these peak values occur coincide at a value slightly lower than 1.0 on the normalized period axis, a statistic that had previously varied greatly by earthquake magnitude. The B curves illustrated in Fig. 15 may allow

Seismic Actions Due to Near-Fault Ground Motion, Fig. 13 Comparison of mean values of the strength reduction factor with the Veletsos-Newmark-Hall design equations for: (a) all earthquakes (M_w 5.6–7.6), (b) moderate earthquakes (M_w 5.6–6.3), (c) moderate-to-large earthquakes (M_w 6.4–6.7), and (d) large earthquakes (M_w 6.8–7.6); $\mu = 2.0$, 4.0, 8.0, and $\zeta = 5\%$ (Reprinted from Mavroeidis et al. (2004). Copyright © 2004 John Wiley & Sons, Inc.)

Seismic Actions Due to Near-Fault Ground Motion, Fig. 14 Calculated damping coefficients for near-fault ground motion records: (a) all earthquakes (M_W 5.6–7.6), (b) moderate earthquakes (M_W 5.6–6.3), (c)

moderate-to-large earthquakes (M_W 6.4–6.7), and (d) large earthquakes (M_W 6.8–7.6) (Reprinted from Hubbard and Mavroeidis (2011). Copyright © 2011 Elsevier B.V.)

for a single set of empirical equations to represent near-fault damping coefficients that are normalized by T_p .

An empirical equation was developed by Hubbard and Mavroeidis (2011) to fit the main behavior of damping coefficients observed in the set containing all records (Fig. 15a). In order to effectively model these B curves, two equations were needed to describe different ranges of the

damping ratio. Equation 6 is designed to be representative of the damping coefficients at normalized periods greater than ~ 0.83 , a normalized period where the peak in value seems to occur. Below this characteristic normalized period, the damping coefficients linearly reduce to one at a normalized period of zero. Damping ratios are represented as fractions instead of whole numbers within the context of Eq. 6:

Seismic Actions Due to Near-Fault Ground Motion, Fig. 15 Damping coefficients for near-fault ground motion records with the period axis normalized with T_p : (a) all earthquakes (M_w 5.6–7.6), (b) moderate

earthquakes (M_w 5.6–6.3), (c) moderate-to-large earthquakes (M_w 6.4–6.7), and (d) large earthquakes (M_w 6.8–7.6) (Reprinted from Hubbard and Mavroeidis (2011). Copyright © 2011 Elsevier B.V.)

$$B = 3.4 \frac{\beta^{1.3}}{(T/T_p)^{1.3}} + 1 \quad \text{for } 0.10 \leq \beta \leq 0.50 \quad (6a)$$

$$B = 2 \frac{(\beta + 0.3)^{1.5}}{(T/T_p)^{1.3}} + 1 \quad \text{for } 0.50 < \beta \leq 1.00 \quad (6b)$$

The empirical expression that was developed through this method is shown in Fig. 16 as a direct

comparison to the computed damping coefficients for the set containing all records. For the considered ranges of damping ratio and normalized period, Eq. 6 provides a model that is conservative without exception. It also does an adequate job of capturing the shape of the curves, ensuring that there are no damping coefficients that are greatly overconservative. In addition, the model remains conservative and captures the behavior of the damping coefficient plots of the different earthquake magnitude groupings

of the dataset (Figs. 15b, c, d) as shown by Hubbard and Mavroeidis (2011).

Summary

This entry focuses on the description of seismic actions due to near-fault ground motions. Particular emphasis was given on synthesizing broadband near-fault ground motion time histories for earthquake engineering applications, using a simple mathematical model for the representation of the coherent ground motion component and a physical model of the seismic source for the description of the incoherent seismic radiation. In addition, recommendations on design spectra, strength reduction factors, and damping coefficients were made for engineering analysis and design in the near-fault region. This included the normalization of the period axis with respect to the period of the ground velocity pulses. The pulse period is controlled by the rise time on the fault plane and scales directly with earthquake magnitude.

University London, London, UK

Synonyms

Concrete bridges; Modal analysis; Nonlinear analysis; Seismic loading

Introduction

Bridges are deceptively simple systems, since they are typically single-storey structures

wherein the horizontal members (the deck) can often be modeled either as a continuous beam or as a series of simply supported beams. In fact, the continuous beam might be a valid approximation in seismic analysis of bridges if a “spine” model is adopted; in such a model the bridge deck is simulated using 3D beam elements with 6 degrees of freedom (DOFs) at each node, located at the centroid of the cross section. It is worth noting that in gravity load analysis the geometric complexity of the deck is usually represented in the computer model to greater detail, as compared to that used for estimating the seismic response. On the other hand, bridges present peculiarities that are not commonly encountered (or are far less important) in buildings, such as the modeling of bearings, shear keys, and expansion joints, as well as the modeling of soil-structure interaction at all bridge supports, including those at the abutments which can play a major role in some cases.

In the sections that follow, modeling of the various bridge components is first addressed (section “[Modeling of Bridge Components](#)”), followed by an overview of methods currently used for seismic analysis of bridges (section “[Bridge Analysis Methods](#)”), which is a topic that is also addressed in other articles of the encyclopedia; section “[Bridge Analysis Methods](#)” also includes the presentation of a case study that illustrates the modeling and analysis procedures described in the previous sections, while both sections “[Modeling of Bridge Components](#)” and “[Bridge Analysis Methods](#)” include specific modeling examples and selected results. Finally some concluding remarks are provided in section “[Summary and Concluding Remarks](#).” Methods of seismic analysis are presented in various parts of the encyclopedia (e.g., article by Vayas and Iliopoulos (2014) focusing on modeling of steel and composite bridges). Hence, the focus herein is on analysis of concrete bridges, wherein some specific issues arise as discussed in the following; of course, several of the described models and techniques are also applicable to bridges made of other materials.

Modeling concrete bridges for seismic design purposes should always take into account the

intended plastic mechanism, which, contrary to buildings, involves primarily yielding in the vertical members, i.e., the piers, while seismic energy dissipation can also take place in the bearings; in a small number of (important) bridges, supplementary damping devices (such fluid or friction dampers) are provided and have to be accounted for in the analysis. In practical design applications bridges are analyzed in the elastic range, and any inelasticity (material nonlinearity) effects, wherever entering of some members in the inelastic range under the design earthquake is allowed, are accounted for by simply reducing the design response spectrum by a “behavior” (or force reduction) factor. However, special types of bridges have been analyzed using advanced inelastic analysis tools (typically as a verification of an initial design based on the results of equivalent elastic analysis), and in general, inelastic analysis methods are gaining ground in recent years. Therefore, an attempt is made herein to present some basic concepts and models suitable for inelastic analysis, with emphasis on those that are better suited for practical application.

Modeling of Bridge Components

Deck

In concrete bridges the deck can have various forms, i.e., solid slab, voided slab, beams (usually precast I-beams) with cast in situ top slab, box girder (single-cell or multicell), and other, less common, ones. The material used is typically prestressed concrete, except for some short span bridges with slab-type deck, where ordinary reinforced concrete can be used.

Very important, both for the seismic behavior of the bridge and for its modeling, is the type of pier to deck connection. There are three basic options in this respect:

- **Monolithic connection:** Very common in slab bridges and box-girder bridges, especially when the cantilever method of construction is used in the latter.

Seismic Analysis of Concrete Bridges: Numerical Modeling, Fig. 1 Pier region of a bridge with deck consisting of precast posttensioned beams and cast in situ slab continuous over the piers

- **Bearing connection:** The deck rests on the piers through two or more bearings, which in the case of modern concrete bridges are typically elastomeric bearings; this is the usual type of connection in the case of beam-type decks and also in box-girder bridges when the incremental launching method of construction is used.
- **Mixed type of connection:** Some piers (typically the taller ones) are monolithically connected to the deck, whereas others (typically the squat ones) have bearing connections. This is a fairly new solution, which has advantages when bridge configurations with substantially unequal pier heights have to be used (e.g., in ravine bridges).

In the case of bearing connections (very common in older concrete bridges), it is clear that the deck does not carry moments due to lateral (seismic) loading nor forms part of the energy dissipation mechanism of the bridge. An exception is the case of continuity slabs, i.e., the parts of a top slab in beam-type decks that continue over the piers (whereas beams terminate on each side of the pier), hence providing a continuous deck (Fig. 1). For these regions modern codes like Eurocode 8-2 (CEN 2005a) allow formation of plastic hinges (in bending about the transverse axis, see Fig. 1). When the focus of the analysis is on the response to the design earthquake and inelastic behavior is allowed and anticipated,

actual hinges can be introduced beforehand at these locations.

In the usual case that the deck remains elastic under the design seismic action, it can be modeled with elastic elements of any appropriate type: beam-column elements forming frames or grillages or even shell elements. For seismic analysis the recommended approach is the use of 3D beam columns (spine model), which is the simplest option and generally an adequate one for the purposes of this analysis. Relevant guidelines like those of ACI 341 (2014) and FHWA (2006) recommend four to five elements per span, but usually more elements are used in practice, since these are elastic members and do not noticeably affect the computational demands. Besides, prestressed concrete members like beams and box girders often have cross sections that vary along the span (thicker webs of beams and box girders toward the piers, where shear forces are maximum); hence, the 3D beam elements should be arranged in such a way that they properly reproduce this gradual change in geometry. Moreover, since masses required for the dynamic analysis of the bridge are typically lumped at the nodes of the model (even when uniformly distributed masses are automatically calculated from the geometry of the elements), use of a sufficient number of elements leads to a more accurate representation of the mass distribution in the bridge and hence of its dynamic characteristics.

In the case of *monolithic* connections, deck-to-pier joints carry bending moments due to seismic loading, and in principle, parts of the deck may become inelastic. However, in most cases the strength of the deck that is governed by the substantial gravity loading on the bridge plus traffic loads (very high in railway bridges) is clearly higher than that of the pier that is typically governed by seismic moments in medium to high seismicity areas; hence, the deck remains in the elastic range and the previous comments apply. In this case, accurate modeling of box girders requires accounting for shear lag (nonuniform distribution of the longitudinal stress across the flange width due to the shear deformations within the flange); the FHWA (2006) manual specifies that the flexural stiffness of the superstructure taken

about a transverse axis should be reduced near piers when there is moment transfer between the superstructure (deck) and the pier, without providing values for this reduction. According to the ATC-32 report (ATC 1996), stiffness in these regions is based on an effective width that should be no greater than the width of the column plus twice the cap beam depth. If this width is practically equal to the entire width of the superstructure, no reduction in stiffness due to shear lag is required in the model.

An example is shown in Fig. 2 depicting the spine model of an overpass bridge (Kappos et al. 2013a) with monolithic pier to deck connections and free sliding connections at the abutments. It is seen that, depending on the length of the span, up to 11 3D beams have been used. The thickening of the webs of the box-girder section toward the end of the spans is properly modeled in the software used, SAP 2000 (CSI 2011). Figure 2 also conveys an idea of what the model would look like in case shell elements were used. As shown in a study by Kappos et al. (2002), it is possible to achieve a good match of the dynamic characteristics of a bridge modeled using shell elements, using a simple spine model; the match was particularly good (differences in significant natural periods between 4 % and 11 %) when reduced flexural rigidity was specified for the 3D beam elements close to the monolithic connection. That study also confirmed that it is not necessary to use too many elements for the deck; in fact a model involving 488 3D beam elements predicted almost identical dynamic characteristics (periods and mode shapes) as another one using only 77 elements (8 per span).

The value of *flexural rigidity* (EI) to be assigned to the elements used for modeling the deck depends on the material used. In the usual case of prestressed concrete, it is allowable to assume negligible cracking and use the value for the gross cross section (EI_g). In ordinary (non-prestressed) reinforced concrete decks, EI should account for cracking effects. Recommended values in Caltrans (2013) are 50–75 % of EI_g ; the lower bound represents lightly reinforced sections and the upper bound represents heavily reinforced sections.

The results of seismic analysis in the transverse direction of a bridge with box-girder deck will be influenced by the assumption made regarding the *torsional* stiffness of the deck (which is substantial, as opposed to that of “open-type” orthotropic decks like beams with top slab). It is recommended to assume 20 % of the uncracked value, based on the ratios ($10 \div 30$ %) of cracked-to-uncracked torsional stiffness estimated by Katsaras et al. (2009).

In between the aforementioned simple (spine) and complex (shell) modeling approaches for the deck is the *grillage* model, i.e., a horizontal planar system of longitudinal and transverse 3D beams, as shown in the example of Fig. 3, referring to a ravine bridge with a top slab on posttensioned I-beams supported through laminated elastomeric bearings, studied by Ntotsios et al. (2009). The longitudinal members of the grillage have the properties of the I-beams and the tributary part of the slab, the transverse elements above the piers have the properties of the actual transverse beams in the actual bridge, while the intermediate four transverse elements of the grillage represent the coupling of the longitudinal beams in the transverse direction due to the presence of the deck. Grillage models are particularly suited for slabs or orthotropic decks like that of Fig. 3 and provide a good balance between accuracy and practicability. They are not very easy to set up nor offer particular advantages over the spine model in the case of box-girder sections. An important issue here is the modeling of the torsional stiffness of the deck which cannot be estimated from the properties of the individual elements of the grillage but rather should be derived for the entire box girder and then distributed among the longitudinal members. In case the grillage model is used for solid slab decks, it is recommended to add diagonal braces to account for the interaction between longitudinal and transverse deck action due to Poisson effects, which cannot be neglected (as in the case of orthotropic decks with primary girders, see Vayas and Iliopoulos (2014) for orthotropic composite decks). More details on the input parameters required for deck modeling with grillages (flexural and torsional rigidities, shear areas)

Seismic Analysis of Concrete Bridges: Numerical Modeling, Fig. 2 Finite element modeling of an overpass bridge with a box-girder superstructure monolithically connected to the piers (Kappos et al. 2013)

Seismic Analysis of Concrete Bridges: Numerical Modeling, Fig. 3 Grillage model and detail of the connection between the deck and the pier (*above*) for a ravine bridge with beam with top slab deck (*below*)

can be found in Chapter 2, of the recent book by Kappos et al. (2012). In that chapter a brief discussion of some advanced topics like the effects of skewness and curvature in plan and/or in elevation on the seismic response, and the verification of deck deformation demands when this is necessary for seismic assessment, can also be found.

Piers and Their Foundations

Piers commonly used in concrete bridges are of the following types:

- Single columns with solid circular or (less frequently) rectangular section
- Single columns with hollow circular or rectangular section
- Multicolumn bents (frame-type piers, running in the transverse direction of the bridge)
- Wall-type piers (usually of large dimensions, especially in the transverse direction)
- Braced piers (usually V shaped)

It is noted that hollow rectangular piers are typically of large dimensions (could reach 7 m or more in the transverse direction), and their structural behavior is closer to that of walls, rather than of hollow circular columns.

Geometric Considerations

Single-column piers, whether solid or hollow, are generally modeled as “sticks” using beam-column elements; four to five elements are usually enough, unless complex geometries (e.g., flared columns) are involved. As shown in Fig. 4, the top element of the column is connected via a rigid link to the centroid G of the deck section (which is the location of the corresponding horizontal element); in most software packages there is no need for specifying a different element, but rather the top element of the column extends up to G , and its end portion is specified as a rigid offset. In the common case of columns monolithically connected to the box girder of the deck, there is no need for additional elements in the column, but when the box girder is supported on bearings (which will be the case at the abutments), it is necessary to introduce transverse elements extending from the first to the last bearing and link these to the end node of the deck model using rigid links (see bottom right of Fig. 2).

As shown in Fig. 4, the moment distribution along the height of the pier is influenced by the rotational restraint at the top, which in turn depends on the torsional rigidity of the deck. This is substantial in the case of box girders

Seismic Analysis of Concrete Bridges: Numerical Modeling, Fig. 4 Pier modeling and transverse response accounting for the torsional stiffness of the deck

(as in Fig. 4) and low in the case of precast beams with top slab and other similar, “open-type,” sections.

Multicolumn bents are naturally modeled as 2D frames, again with beam-column elements, each of which has the properties of the corresponding member (column or cap beam). It is worth noting that although columns usually have circular sections, cap beams are rectangular. Rigid offsets at the element ends properly capture the effect of the finite size of the beam-column joints that are quite massive members in bridges. In case the cap beam is monolithically cast with the deck, the torsional resistance of the top of the bent is substantially higher than that of the cap beam alone; Aviram et al. (2008) recommend multiplying the torsional resistance of the cap beam by 10^2 . Clearly this does not apply in the case that the deck is bearing-supported on the cap beam. *V-shaped* piers are modeled in a similar way, but of course, vertical elements are inclined rather than upright.

There are several options available for modeling *wall-type* piers and the aspect ratio is an important parameter in this case. The simpler model is clearly the stick one, previously mentioned for the case of single-column piers. Decks are usually bearing-supported on wall-type piers (which are the preferred solution in seismic isolation designs wherein seismic energy dissipation takes place in the bearings and, whenever present, the dampers); hence, it is essential in this case to

add the aforementioned horizontal rigid element at the top of the stick model. A more refined model could consist of a vertical grillage (see notes on grillage models in section “Deck”). The most refined model, feasible only in elastic analysis, is the use of shell elements; an example (not necessarily a recommended one, unless for research purposes) is shown in Fig. 5; a mesh of 18,885 shells was set up for the 3-span bridge, keeping the aspect ratio of the shells rather low at 1.2, since these elements perform best when their shape is close to square. As noted in section “Deck,” the main normal modes of that bridge were captured with reasonable accuracy using a simple spine model with only 77 beam-column elements (Kappos et al. 2002).

Stiffness Considerations

Even in elastic analysis of reinforced concrete (R/C) piers for seismic loading, it is essential to account for the effect of cracking, to make sure that displacements are not underpredicted. Practically all existing codes adopt approximate values of the pier stiffness, corresponding to yield conditions, and this stiffness is assumed as known when design seismic actions (e.g., modal forces) are estimated. These approximate values are either very rough estimates, like the $0.5 EI_g$ (50 % of uncracked section rigidity) adopted by both Eurocode 8-1 (CEN 2004) and AASHTO (2010), or slightly more sophisticated ones taking into account the level of axial loading on the pier

Seismic Analysis of Concrete Bridges: Numerical Modeling,

Fig. 5 Finite element (*shell*) mesh in the pier to deck connection area of a bridge with box-girder superstructure monolithically connected to hollow rectangular piers (Kappos et al. 2002)

Seismic Analysis of Concrete Bridges: Numerical Modeling,

Fig. 6 Effective stiffness of cracked reinforced concrete circular sections (AASHTO 2010)

(which, in general, is not significantly affected by seismic actions) and/or the reinforcement ratio.

Eurocode 8-2 for Seismic Design of Bridges (CEN 2005a) in its (informative) Annex C suggests the following relationship for the effective moment of inertia of R/C ductile columns:

$$I_{\text{eff}} = 0.08 I_g + I_{\text{cr}} \quad (1)$$

where the cracked section inertia can be calculated as the secant value at yield (M_y is the yield moment and ϕ_y the yield curvature, E_c the concrete modulus)

$$I_{\text{cr}} = M_y / (E_c \cdot \phi_y) \quad (2)$$

Obviously, I_{cr} can only be estimated from Eq. 2 when the pier has been designed, so that both strength and yield curvature can be calculated; hence, use of these relationships is feasible only when iterative elastic analyses, or inelastic analysis, are used.

The Caltrans Seismic Design Criteria (2013) adopt the same concept as EC8-2 (secant value at yield), the only exception being that the $0.08 I_g$ term (accounting for tension stiffening effects) is not included in Eq. 1. As an alternative, the Caltrans Criteria allow the calculation of effective stiffness as a function of the axial load ratio and the pier reinforcement ratio from graphs provided by Priestley et al. (1996); diagrams like that of Fig. 6 can be directly implemented for carrying

Seismic Analysis of Concrete Bridges: Numerical Modeling, Fig. 7 Lumped plasticity model (a) basic configuration; (b) hysteresis law for springs

out elastic analysis, assuming a reasonable reinforcement ratio (e.g., $A_{st}/A_g = 0.01$, which is the usual minimum reinforcement ratio), while, in principle, analysis should be repeated if the resulting reinforcement is substantially different.

Nonlinear Models for Piers

As mentioned in section “[Introduction](#),” the most common plastic mechanism on which seismic design is based is that involving inelastic response of the piers. Therefore, inelastic (material nonlinear) modeling of piers is important, not only for research but also for practical assessment purposes (which includes assessing an existing, probably substandard, bridge as well as a newly designed bridge that is important enough to warrant this additional design effort). Space limitations do not allow a detailed treatment of this important issue, and only a brief overview of the main available models will be provided herein; more detailed information on nonlinear modeling of bridge piers and several case studies can be found i.a. in the recent book by Kappos et al. (2012).

Nonlinear models for piers can be classified into three categories:

- Lumped plasticity models
- Distributed plasticity models
- Continuum models

Several subcategories can be defined for each of the above, as briefly discussed in the following.

Lumped plasticity models, also known as “point-hinge” models, are based on the simplifying assumption that all inelastic behavior takes place at the plastic hinge points that are typically located at the member ends. This concept can be materialized in different ways, the most efficient one consisting in inserting two nonlinear rotational springs at the element ends, as shown in Fig. 7a; more accurately, the springs are inserted at the ends of the rigid offsets located at the element ends to model the finite width of joints (e.g., between the cap beam and the column, in a multicolumn bent). All post-yield flexural deformation takes place in these springs, whereas the remainder of the beam-column element remains elastic throughout; it is emphasized that the flexural rigidity EI of the “elastic” element should account for cracking effects, as discussed in section “[Stiffness Considerations](#).” The (local) stiffness matrix for this lumped plasticity element, relating chord rotations at the ends to the corresponding bending moments, can be readily set up assuming a series connection between the springs and the beam, hence adding the flexibility matrices of each component, i.e.,

$$[F] = [F_e] + [F_s] = \begin{bmatrix} \frac{L}{3EI} + \frac{1}{K_{Si}} & -\frac{L}{6EI} \\ -\frac{L}{6EI} & \frac{L}{3EI} + \frac{1}{K_{Sj}} \end{bmatrix} \quad (3)$$

where K_{si} and K_{sj} are the stiffnesses of the springs at ends i and j , which are assumed for simplicity to be uncoupled (no off-diagonal terms K_{sij}) and can be different, e.g., when one end has yielded while the other is still in the pre-yield range. The main advantage of this simple model is that K_s values can be defined on the basis of any constitutive law, whether simple or complex. Figure 7b shows a typical moment versus rotation hysteresis law (with stiffness degradation) that can be applied to either spring; note that prior to exceeding the yield moment the springs are rigid ($K_s = \infty$), hence all elastic deformation takes place in the elastic member. The 2×2 flexural stiffness matrix relating end moments to chord rotations can be easily derived by inverting $[F]$ and then transforming to the 6×6 matrix including the rigid body modes and the axial deformations (axial stiffness EA is usually assumed to remain unaffected by flexural yielding).

Bridge piers, in particular those of the wall type, develop significant shear deformations subsequent to shear cracking, which may occur before or after flexural yielding. In the lumped plasticity context, shear deformations can be treated either in a simplistic way by using the stiffness matrix of a Timoshenko beam (involving GA' terms in addition to EI ones) and a rough reduction factor for GA' , or, more rigorously, by introducing additional springs at the ends representing the relationship between shear force and shear deformation; the issue of inelastic shear is discussed later on in relation to another model. Another important source of deformation in R/C piers, especially those with substandard detailing with respect to earthquake requirements, is *bond slip*, which can give rise to substantial local rotations at the member ends ("fixed end rotations"). This effect can either be modeled indirectly by decreasing the stiffness of the $M - \theta$ law (Fig. 7b) at the member ends, something that requires proper calibration, or be modeled directly by introducing additional rotational springs to the model of Fig. 7a.

Despite their crudeness, lumped plasticity models (first develop in the 1960s) remain quite popular due to their simplicity, as well as the fact

that they can relatively easily account for the effects of shear, as well as of bond slip, and are easier to calibrate against experimental results than other, more sophisticated (and complex), models.

Distributed (or spread) plasticity models, still of the beam-column type, drop the assumption of point hinges and directly account for the spread of inelasticity along the bridge member, hence leading, in principle, to more accurate results. There are several different approaches in this respect, i.e., inelastic response can be monitored at several predetermined sections of the element and the stiffness matrix be synthesized on the basis of the tangent stiffness of each such section, or variable length plastification zones be defined, typically at the member ends, assuming the rest of the element is quasi-elastic (as in lumped plasticity models). The latter option retains some of the simplicity of point-hinge models while being more rational and, in principle, accurate and will be described in the following.

A recent spread plasticity model (Mergos and Kappos 2012) accounting for inelastic response in all mechanisms (flexure, shear, bond slip) is shown in Fig. 8. The length of the plastified zones at the ends (respective rigidities EI_A and EI_B) is defined on the basis of the moment diagram of the element and the corresponding yield moments, e.g., the left zone has a length $\alpha_A \cdot L$, where

$$\alpha_A = \frac{M_A - M_{yA}}{M_A - M_B} \leq 1 \quad (4)$$

The flexural stiffness matrix can be set up using the principle of virtual work for the case of members with variable cross section. The current rigidities are calculated from the moment versus curvature relationship at each member end. Models with more than three parts have been proposed but are not deemed appropriate for practical application.

A similar procedure can be followed in the case of the shear sub-element (Fig. 8d), which represents the hysteretic shear behavior of the R/C member prior and subsequent to shear cracking, flexural yielding, and yielding of the shear reinforcement. In this case, the current shear

Seismic Analysis of Concrete Bridges: Numerical Modeling,

Fig. 8 Distributed plasticity model: (a) geometry of R/C member; (b) beam-column finite element with rigid arms; (c) flexural sub-element; (d) shear sub-element; (e) anchorage slip sub-element

rigidities (GA_A , GA_B) are calculated from the $V - \gamma$ (shear versus shear deformation) curves at each end, details of which are given in Mergos and Kappos (2012). After determining the distribution of GA along the R/C member at each step of the analysis and by applying the principle of virtual work, the coefficients of the flexibility matrix of the shear sub-element are given by the following equation:

$$f_{ij}^{sh} = \frac{a_{As}}{GA_A \cdot L} + \frac{1 - a_{As} - a_{Bs}}{GA_M \cdot L} + \frac{a_{Bs}}{GA_B \cdot L} \quad (i, j = A, B) \quad (5)$$

Finally, rotations due to slip at the end anchorages are captured with the simple slip sub-element of Fig. 8e that consists of a rigid bar with two uncoupled nonlinear springs at the ends. The $M - \theta_{slip}$ skeleton curve is derived assuming uniform bond stress along different segments of the anchored reinforcement bar (details in Mergos and Kappos 2012).

In the previously presented models, the element stiffness matrix in the post-yield range is set up on the basis of EI values that are estimated from predefined constitutive laws relating bending moment to either end rotation or end curvature; when axial (EA) and shear (GA) rigidities are not taken as constant, their values are estimated from similar predefined laws (e.g., $V - \gamma$). Another option is the *fiber model*, wherein the stiffness parameters are not estimated from predefined laws, but rather from moment – curvature analysis (and, far less often, shear force versus deformation analysis) of a number of “monitoring” or “control” sections, which are divided in a number of “fibers” (in the general, biaxial, case, these are squares or rectangles rather than horizontal fibers), using Bernoulli’s principle and the stress-strain constitutive laws of the pertinent materials, i.e., confined and unconfined concrete (for the core and the cover, respectively) and steel bars, as shown

Seismic Analysis of Concrete Bridges: Numerical Modeling, Fig. 9 Discretization of R/C member using the fiber approach

in Fig. 9 (Kappos et al. 2012). The model has been implemented in point-hinge models but has found its main use in distributed plasticity models, wherein four (Fig. 9) or more sections are “monitored” and the element stiffness matrix is set up assuming linear variation of stiffness (or flexibility) between monitoring sections; the latter are typically taken as the end sections and the Gauss points used in the integration required for deriving the element stiffness matrix (e.g., using the Gauss-Lobatto quadrature scheme).

A rigorous application of the fiber model involves a number of difficulties, and different approaches have been put forward, some of them based on the stiffness approach (and involving displacement shape functions) and others on the flexibility approach (involving force shape functions, which do not change in the inelastic range); hybrid procedures have also been used. The flexibility approach is numerically more advantageous but computationally more demanding. Details of all these procedures fall beyond the scope of this entry and can be found in the literature (e.g., Fardis 1991; Kappos et al. 2012). However, it has to be emphasized here that although the fiber approach is more rigorous than the “phenomenological” approaches based on predefined force – deformation relationships,

it is not necessarily more accurate than the latter, except in the case of R/C members with negligible effect of shear and bond-slip deformations, which is not very common, even in well-designed bridge members. For instance, a pier usually has such an aspect ratio that shear deformations cannot be ignored. There are versions of the fiber model wherein shear deformations are included (Kappos et al. 2012), but the computational cost involved is particularly high. Finally, because most of the available fiber model-based software packages (like SeismoStruct) include constitutive laws assuming that concrete is initially uncracked, they overestimate the actual stiffness of real bridges (and other structures) that are cracked prior to being subjected to seismic loading (due to shrinkage, traffic and ambient vibrations, and possible previous small earthquakes).

Nonlinear *continuum models* are typically used for research purposes, whose aim is to study in detail the response of critical regions in piers. Material nonlinearity is taken into account using either a “standard” plasticity model or a combination of plasticity and damage models, the latter being able to affect the elastic component of the deformation as (seismic) damage propagates. Geometric nonlinearity is less critical in R/C piers, except for very tall ones. The type of

Seismic Analysis of Concrete Bridges: Numerical Modeling, Fig. 10 Modeling of hollow circular piers with solid elements using different heights and mesh densities

finite elements used can be quite “heavy,” i.e., shell and 3D solid (“brick”) elements have been used for concrete piers. Figure 5 shows an example of using shell elements for both the deck and the piers, but nonlinear behavior was not taken into account in that model.

Figure 10 is taken from a study (Papanikolaou and Kappos 2009) focusing on the effect of confinement on the strength and ductility of solid and hollow piers; solid elements were used for concrete, whose behavior was governed by a sophisticated plasticity model accounting for confinement effects, while line elements embedded to the solid elements were used for the reinforcement (transverse reinforcement consisted of spiral or hoop circular reinforcement, with or without transverse links). It is seen that the axial load versus axial deformation curves resulting from the “coarse” mesh are not substantially different from those from the dense mesh; it is worth pointing out that an upper limit of about 6,000 solid elements was found, beyond which the computational cost and volume of results were excessive, which is a good indicator of the type of models that can be analyzed in such a context. Further examples of applications of continuum models to concrete pier components can be found in Kappos et al. (2012).

Soil-Structure Interaction Effects

A key aspect in proper modeling of piers (whether inelastic or equivalent elastic) is

capturing the effect of foundation compliance, i.e., of the fact that pier foundations, especially the shallow but also the deep ones, like piles, do not provide full fixity to the base of the pier, but displace (horizontally), rotate, and even settle (vertically), as the bridge is subjected to seismic loading. Large-size foundations have also the effect of modifying the seismic input to the structure (“kinematic” interaction or “wave scattering” effect), but this issue is not further addressed herein. The interaction of the foundation ground with the bridge substructure (the piers and their foundations) does not only modify the fixity conditions but also increases the damping (“radiation” damping at the ground-foundation interface); in simplified analysis this can be safely ignored, but there are ways to explicitly include it, such as the addition of dash-pot elements at the base of the piers.

A commonly adopted practical approach for calculating the pseudo-static interaction between the bridge foundation and the soil is the *Winkler spring* model, wherein the soil reaction to the foundation movement is represented by independent (linear or nonlinear) unidirectional translational spring elements. In the case of surface foundations, the vertical springs are distributed below the surface of the footing, while in pile foundations horizontal springs are distributed along the pile shaft. Although approximate, Winkler formulations are widely used not only

because their predictions are in good agreement with results from more rigorous solutions but also because the variation of soil properties with depth can be relatively easily incorporated. Moreover, they are efficient in terms of computational time required, thus allowing for easier numerical handling of the structural inelastic response, where this is deemed necessary.

In the case of *surface foundations*, a simple system of three translational (two horizontal, x and y , one vertical, z) and two (less often three) rotational springs can be used at the base of the footing; the spring constants for the x , y , and z springs can be estimated from relationships (ASCE 2007) derived from the solution of the problem of a rigid plate resting on the surface of a homogeneous half-space:

$$\begin{aligned} K_x &= \frac{GB}{2-v} \left[3.4 \left(\frac{L}{B} \right)^{0.65} + 1.2 \right] \\ K_y &= \frac{GB}{2-v} \left[3.4 \left(\frac{L}{B} \right)^{0.65} + 0.4 \frac{L}{B} + 0.8 \right] \\ K_z &= \frac{GB}{2-v} \left[1.55 \left(\frac{L}{B} \right)^{0.75} + 0.8 \right] \end{aligned} \quad (6)$$

where G is the shear modulus of the ground, v the Poisson ratio (0.35 for unsaturated soils and 0.5 for saturated soils), L the larger dimension of the (rectangular) footing, and the smaller one; similar relationships are given in ASCE (2007) and FHWA (2006) for the rotational springs. These relationships are particularly convenient to use since they only include very fundamental properties of the soil, which can always be estimated (e.g., the initial modulus G_0 can be estimated from the shear wave velocity and the specific weight of the soil). However, an upper and lower bound approach to defining stiffness and (in nonlinear models) capacity is recommended because of the uncertainties in the soil properties and the static loads on the foundations of existing bridges. The large-strain effective shear modulus, G , can be roughly estimated on the basis of the anticipated peak ground acceleration (PGA); for regions of low-to-moderate seismicity, a value of $G = 0.5 G_0$ is recommended, while

for regions of moderate-to-high seismicity, $G = 0.25 G_0$ is suggested (FHWA 2006).

In *pile foundations* the mechanical parameters for the springs are frequently obtained from experimental results (leading to P-y curves for lateral and N-z curves for axial loading) as well as from very simplified models. A commonly used P-y curve is the lateral soil resistance versus deflection relationship proposed by the American Petroleum Institute (API):

$$P = 0.9p_u \tanh \left[\frac{kH}{0.9p_u} y \right] \quad (7)$$

where p_u is the ultimate bearing capacity at depth H , y is the lateral deflection, and k is the initial modulus of subgrade reaction. The tip of the pile can either be modeled using a vertical spring (with a carefully selected axial stiffness) or assumed to be vertically fixed but free to rotate.

Figure 11 shows an example (Kappos and Sextos 2001) of modeling a pile group using Winkler springs with initial properties calculated from Eq. 7. This is a fully inelastic model wherein both the piles and the pier (modeled using the lumped plasticity approach, but with several elements for each pile) can yield; in practical applications equivalent linear properties (based on secant stiffness at the estimated maximum displacement) are often used, especially for the soil. The limitations of the P-y approach are discussed in detail in Kappos et al. (2012), where an overview of more advanced soil-bridge interaction (kinematic and inertial) models is also provided. It will only be mentioned here that despite the abundance of models and software, nonlinear analysis wherein both the bridge and the foundation ground are modeled with nonlinear models is not only cumbersome but often leads to convergence problems; hence, explicit treatment of nonlinearity should be confined where the main interest lies, typically in the piers and perhaps in the piles (cf. Fig. 11).

Abutments and Backfills

There are two common types of bridge abutments:

Seismic Analysis of Concrete Bridges: Numerical Modeling, Fig. 11 Modeling of soil-pile foundation-pier system using Winkler springs

- Seat type (the deck is bearing-supported on the horizontal seat of the abutment; see Fig. 2 bottom right)
- Integral or diaphragm type (abutment monolithically connected to the end of the deck)

The modeling of the abutment system, which also includes the wing walls and the foundation (footing or piles) can vary from very simple to very complex, depending on the situation. Some common cases are briefly discussed in the following.

Integral- or *diaphragm-type* abutments are always included in the model of the bridge, as a continuation of the deck model; in addition to the body of the abutment, they also include the foundation, which typically consists of piles (often relatively flexible ones). It is essential that the flexibility of the abutment foundation be modeled; otherwise the displacements of the integral bridge are seriously underestimated; besides problems with earthquake analysis, failure to capture the flexible end supports of the bridge also results in unrealistic stresses from

Seismic Analysis of Concrete Bridges: Numerical Modeling, Fig. 12 Modeling of abutment system and resulting pushover curves

temperature variations and shrinkage of concrete. In addition to the foundation, the backfill and the embankment have to be accounted for in the model, especially in short bridges with stiff deck; a concept usually adopted in these cases is the “effective” (or “critical”) length of the embankment, whose properties are calculated and then introduced as springs (discussed later in this section) at the end of the elements representing the integral abutment.

Seat-type abutments can be modeled in a simple way, as shown in Fig. 2, i.e., by just including in the model the bearings (as springs, see section “[Bearings](#)” for property definition) of the abutment seat; so long as the end connection of the bridge is dominated by the properties of the bearings (in modern concrete bridges these are either elastomeric or pot bearings that can slide in all directions, see section “[Bearings](#)”), this simple model is quite adequate. If pot bearings are used, even a simple sliding connection (roller support) can be defined in the model; this ignores friction forces at the pot bearings, which are small if monolithic connections or fixed bearings are used elsewhere in the bridge. However, when a longitudinal joint closes, or a shear key blocks the transverse movement of the deck, or the gap between the deck and the abutment stem wall closes (see Fig. 2 bottom right), the abutment-backfill system is activated and significant forces

can develop at the bridge ends; further movement (in either direction) can be captured by the model only if the flexibility of the system, which includes both concrete members and the backfill soil, is modeled.

In abutments the important aspects of soil-structure interaction (section “[Soil-Structure Interaction Effects](#)”) are modeled in practice-oriented applications through a system of linear or nonlinear *springs* at the ends of the bridge. The properties of the springs can best be defined by an analysis of the abutment-backfill system, preferably accounting for nonlinear effects directly, or at least by proper selection of reduced properties (e.g., estimates of G of the ground consistent with the expected deformations). Figure 12 shows the modeling of an abutment system (Kappos and Sextos 2009); the abutment wall is modeled with 2D shell elements, while the piles with frame elements supported on (depth dependent) nonlinear horizontal springs. In the vertical direction, friction springs were used along the piles and an appropriate vertical stiffness was introduced with the use of a (compression only) spring at the tip of the piles; a simpler model was also analyzed wherein infinite vertical stiffness was assumed (tip displacements restrained). On the right of Fig. 12 are shown the *pushover curves* (i.e., seismic force versus monitoring point displacement) derived for the transverse direction

(force F_y), wherein the behavior of the abutment system is dominated by the nonlinear response of the piles. For investigation purposes, the analysis was performed both for soft soil conditions (which was the actual case in the specific abutment) and for the case of a significantly stiffer supporting soil. These pushover curves reveal the sensitivity of the abutment response to the soil conditions, as well as the importance of accounting for all possible failure modes in the analysis (shear failure of the piles limits the deformation capacity, i.e., the ductility, of the entire system).

Equivalent linear or nonlinear springs based on the stiffness defined by curves like those in Fig. 12 can be used for modeling abutments to which the deck forces are directly transferred (due to the previously mentioned reasons). A full-range model, covering all stages of the response, should include two (nonlinear) springs in series, one representing the stiffness of the bearings and one the stiffness of the abutment system; a gap element (with the width of the longitudinal joint of the bridge) should be added if analysis is carried out in a single run; otherwise separate analyses with open and closed joint should be carried out (a usual practice in the USA).

In lieu of carrying out a proper analysis of the abutment, simplified procedures can be used for estimating a reasonable stiffness (and, in nonlinear analysis, strength) for the abutment. Arguably the most popular procedure is that prescribed in Caltrans (2013), wherein the *longitudinal* stiffness can be calculated from the initial embankment fill stiffness $K_i \approx 28.7 \text{ kN/mm}$ (m width of the wall), and this has to be adjusted proportionally to the backwall (or diaphragm) height (h):

$$K_{\text{abut}} = K_i \times w \times (h/1.7) \quad (8)$$

where w is the projected width of the backwall or diaphragm, for seat and diaphragm abutments, respectively, and $(h/1.7)$ is a proportionality factor based on the 1.7 m height of the diaphragm abutment specimen tested at UC Davis (the actual relationship is not linear, but so far there is no sufficient data to develop a more sophisticated

one). The aforementioned K_i applies to well-compacted backfills as required by Caltrans (2013); otherwise it should be reduced by 50 %. The ultimate abutment load was assumed to be limited by a maximum static soil passive pressure of 240 kPa; the latter is multiplied by the corresponding surface, e.g., the product of the backwall width and height in seat-type abutments as well as the proportionality factor $(h/1.7)$. The stiffness value for Eq. 8 applies when the elastic response of the bridge is dominated by the abutments; when this is not the case, Caltrans prescribes reductions depending on the ratio of the longitudinal displacement demand at the abutment (from elastic analysis) to the effective longitudinal abutment displacement at idealized yield (ratio of strength to stiffness).

In the *transverse* direction, a nominal abutment stiffness equal to 50 % of the elastic transverse stiffness of the adjacent bent can be used; this nominal stiffness has no direct correlation or relevance to the actual residual stiffness (if any) provided by the failed shear key but is meant to suppress unrealistic response modes associated with a completely released end condition.

Clearly, a full model for the abutment-backfill system should also include the backfill soil, as well as part of the embankment that is activated during the seismic excitation of the bridge; as mentioned previously, the latter is important in the case of short bridges (like two-span overpasses) wherein the embankment plays a key role in the seismic response of the bridge. In particular, consideration of the abutment-soil system participating mass has a critical effect on the mode shapes and consequently the dynamic response of the bridge. The critical length L_c of the embankment to be considered in the analysis can be estimated from the relationship (Zhang and Makris 2002):

$$L_c \approx 0.7 \sqrt{SB_c H} \quad (9)$$

where S is the slope of the embankment, H its height, and B_c its width at the crest. It should be borne in mind that L_c actually changes with the level of the seismic action, but this is difficult to capture in practical analysis.

Seismic Analysis of Concrete Bridges:

Numerical Modeling,
Fig. 13 Modeling of abutment and backfill system using 3D finite elements

An example of a “heavy” finite element model of the entire system is shown in Fig. 13 from Kappos et al. (2012) wherein further examples and details can be found. Results of analysis of a number of typical abutment and backfills using sophisticated models such as that of Fig. 13, which considered the soil (backfill, embankment, and foundation) as the nonlinear material mechanism, have shown that both the stiffness and the strength estimated according to the pre-2013 Caltrans provisions (adopting $K_i = 11.5$ kN/mm/m, i.e., 60 % lower than the new value) underestimated the values found from the 3D FE models.

So long as the soil behind the abutment has been analyzed and its (macroscopic) stiffness reduced to a spring constant, the entire bridge can be modeled by combining in series the aforementioned translational springs (one for the backfill-embankment system and one for the abutment and its foundation) in each direction of the bridge. More details on modeling abutments and backfills using a system of nonlinear springs can be found in Aviram et al. (2008).

Bearings, Joints, and Shear Keys

Bridge furnishings include a number of components, i.e.,

- Bearings
- Joints
- Parapets – rails
- Waterproofing system

Among these, critical components of the bridge, particularly in an earthquake resistance context, are the bearings and the joints. Modeling of these critical components for seismic analysis is discussed in the remainder of this section, which also covers some other components, normally located close to, or even within, the bearings, i.e., shear keys and damping devices.

Bearings

Bearings are mechanical systems which:

- Transmit loads from the superstructure (deck) to the substructure (piers, abutments)
- Accommodate relative displacements between them

In the past, steel bearings of the pin, roller, rocker, or sliding type have been used, and they are still used in some bridges, in particular steel ones. In modern concrete bridge construction, bearings typically belong to one of the following categories:

- Pot bearings
- Elastomeric (common) bearings
- Elastomeric (special) bearings

Pot bearings (Fig. 14) allow sliding and rotation and consist of a shallow steel cylinder (or “pot”) on a vertical axis with a neoprene disk which is slightly thinner than the cylinder and fitted tightly inside. A steel piston fits inside the cylinder and bears on the neoprene, while flat

Seismic Analysis of Concrete Bridges: Numerical Modeling,

Fig. 14 Pot bearings (www.agom.it): free-sliding (*left*) and transversely guided sliding

Seismic Analysis of Concrete Bridges: Numerical Modeling,

Fig. 15 Laminated bearing with outer steel plates: profiled (*left*) or allowing fixing (EN1337, CEN 2005b)

brass rings are used to seal the rubber between the piston and the pot; the rubber behaves like a viscous fluid, flowing as rotation occurs. Sliding can either take place in any direction or be guided (through a groove and sliding bar system; see Fig. 14-right) in a specific direction. Use of pot bearings is very common, especially at the seats of the abutments.

In general, pot bearings do not have to be explicitly modeled; it suffices to release the corresponding degrees of freedom at the support of the deck.

Common elastomeric bearings are made of elastomer, i.e., either natural or synthetic rubber (e.g., neoprene), which is flexible in shear (low GA) but very stiff against volumetric change. To avoid bulging (lateral expansion that adversely affects the properties of the elastomer) different types of reinforcement are used in the elastomer (fiberglass, cotton, steel). The most common and efficient (and also the most expensive) type of reinforced elastomeric bearings is that reinforced with thin steel plates as shown in Fig. 15; these are constructed by vulcanizing elastomer to these steel plates.

The design of elastomeric bearings is carried out (in European and some other countries) according to the European Standard EN1337 (CEN 2005b). This standard prescribes maximum strains due to vertical load, rotations and horizontal actions, such as loads or displacements, and minimum thickness of the internal and external steel plates. It also prescribes a number of ultimate limit state verifications (limitation of distortion and rotation, tension in the steel plates, bearing stability (buckling), and slip prevention). The procedure for designing a bridge so that the seismic action is resisted entirely by elastomeric bearings on all supports (“seismic isolation”) is prescribed in Chap. 7 of Eurocode 8-3 (CEN 2005a).

Proper modeling of elastomeric bearings is essential in the framework of seismic design. In all cases at least the horizontal shear stiffness (K_h) should be captured, but in more refined models the flexural (K_b) and the axial (K_v) stiffness of the bearings are also introduced in the model. These three stiffness values can be calculated from the following relationships:

Seismic Analysis of Concrete Bridges: Numerical Modeling, Fig. 16 Lead rubber bearing (rectangular section) and corresponding hysteresis law

$$K_h = GA/t_r \quad (10a)$$

$$K_b = 0.329 E_c I / t_r \quad (10b)$$

$$K_v = E_c A / t_r \quad (10c)$$

where t_r is the thickness of the elastomer (not the total height of the bearing) and the other symbols have their usual meaning. The shear modulus G can be taken as 0.9 MPa for static loading and 1.8 MPa for dynamic loading (rubber is a visco-elastic material, i.e., its resistance increases with the loading rate).

Special elastomeric bearings are those that provide the high energy dissipation needed to resist strong earthquakes. The most common types used today are:

- High damping elastomeric bearings
- Lead-rubber bearings (laminated bearings with lead core)

Bearings of the first category can provide fairly high values of effective damping ratio ($\xi_{\text{eff}} \approx 10\text{--}25\%$). The main concern about them is durability, as rubber properties are known to deteriorate with time; of course, companies manufacturing them claim design lives appropriate for normal uses. Lead-rubber bearings (LRB) are laminated bearings with a cylindrical lead core, as shown in Fig. 16; they are either circular or rectangular. The selection of lead as the core

material is due to its high hysteretic energy dissipation (“fat” elastoplastic hysteresis loops under cyclic loading; see Fig. 16 right). In LRBs the equivalent viscous damping ratio can reach quite high values (in the range of 30 %). In addition to damping, the lead core also provides resistance to service lateral loads.

Modeling of special elastomeric bearings is similar to that of common bearings as far as stiffness is concerned (relationships 10), but the additional damping has to be properly introduced in the model. In all types of elastic analysis, a viscous damping ratio higher than that of reinforced concrete (5 %) is introduced, and the corresponding spectra are used to derive the seismic actions; in Eurocode 8 the ordinates of the elastic spectrum for $\xi \neq 5\%$ are estimated by multiplying the reference spectrum by

$$\eta = \sqrt{10/(5+\xi)} \geq 0.40 \quad (11)$$

The value of effective damping ratio to be used can be estimated from (CEN 2005a)

$$\xi_{\text{eff}} = \frac{1}{2\pi} \left[\frac{\sum E_{D,i}}{K_{\text{eff}} d_{\text{cd}}^2} \right] \quad (12)$$

where $\sum E_{D,i}$ is the sum of dissipated energies of all special bearings i in a full deformation cycle at the design displacement d_{cd} and $K_{\text{eff}} = \sum K_{\text{eff},i}$, i.e., the sum of the composite stiffnesses of the

isolator unit and the corresponding substructure (pier) i . For the specific case of LRBs, the dissipated energy $E_{D,i}$ is calculated from the pertinent elastoplastic hysteresis loop (Fig. 16 right).

An interesting type of special bearing, used exclusively for seismic isolation, is the *friction pendulum* shown in Fig. 17, wherein the sliding surface of the bearing is concave; hence, the restoring force is provided by the horizontal component of the structure itself. Sliding on the concave surface is resisted by friction of the contact material which is PTFE (polytetrafluoroethylene, most common commercial name Teflon); the friction coefficient is high initially (hence, no swaying of the superstructure takes place under normal loading conditions) but substantially higher under high velocities induced by earthquake.

The *articulation* of the bridge, i.e., the arrangement of the different types of bearings, is a critical aspect of the design of the bridge, in particular the seismic one. Figure 18 shows an

example of an actual railway bridge wherein a seismic isolation approach was adopted, involving a combination of lead rubber bearings and viscous fluid dampers; it is seen that the LRBs located toward the end of the bridge are movable horizontally, while free sliding pot bearings are used at the abutments.

Supplemental Damping Devices

On several occasions involving large bridges, the amount of damping that can be provided by realistic arrangements of special bearings is not sufficient for limiting displacements to the required limits (recall that long-span bridges are long-period structures and when isolation is used their fundamental period can become very long, more than 3 s). In such cases a more efficient solution can be the use of special damping devices (separate from the bearings) that will supplement the energy dissipation provided by the bearings (high damping or LRB); alternatively, common elastomeric bearings or friction pendulum bearings can be used in combination with the damping devices. The most commonly used devices are

- Viscous fluid dampers
- Steel yielding devices

Viscous fluid dampers are based on the concept (long used in the automotive industry) of forcing through a piston a viscous fluid (usually silicon oil) through an orifice. Another, more recent, alternative are shear panels containing high-viscosity fluids. The constitutive law of such dampers is not restricted to the well-known linear dependence on velocity (through C , the

Seismic Analysis of Concrete Bridges: Numerical Modeling, Fig. 17 Friction pendulum bearing

Seismic Analysis of Concrete Bridges: Numerical Modeling, Fig. 18 Arrangement of bearings in a seismically isolated railway bridge (Kappos et al. 2014)

damping coefficient) but is often nonlinear, of the form

$$F_D = C \cdot |\dot{u}|^\alpha \cdot \text{sgn}(\dot{u}) \quad (13)$$

where F_D is the damping force and α is an exponent between 0 and 1; $\alpha = 1$ corresponds to standard viscous damping, but in practical applications lower values are used since they lead to higher F_D at lower velocities (e.g., in the bridge shown in Fig. 18, $\alpha = 0.15$ was selected for the viscous dampers, which had $C = 5,440 \text{ kN}\cdot\text{s/m}$).

Modeling of viscous fluid dampers can be made using two approaches: in the simpler approach, appropriate for practice-oriented elastic analysis, the dampers are substituted by an effective value which is the sum of the basic damping ξ_0 (typically 5 %) and the contribution of the fluid dampers (having exponent α and damping coefficients C_j). Considering the fundamental mode of the bridge (modal displacements ϕ_i at each mass m_i) and calculating the energy dissipated by the nonlinear dampers in a cycle of sinusoidal motion, it can be shown (Hwang 2002) that

$$\xi_{\text{eff}} = \xi_0 + \frac{\sum_j \lambda C_j \phi_{ij}^{1+\alpha} \cos^{1+\alpha} \theta_j}{2\pi A^{1-\alpha} \omega^{2-\alpha} \sum_i m_i \phi_i^2} \quad (14)$$

where ω is the circular frequency, θ_j is the angle of inclination of the damping device j , λ is a function of the exponent α (tabulated values of λ are given in FEMA 1997), and $u_i = A\phi_i$ (A is the amplitude) are the actual displacements of the masses m_i .

In a more involved, nonlinear, analysis, the viscous dampers can be directly introduced in the model at the particular locations of the bridge wherein they are installed; such elements are available in some software packages but are rarely used in practical design.

Steel yielding devices provide an almost elastoplastic hysteresis loop, and it is possible to get a great variety of damping ratio values by properly selecting the yield displacement and post-yield stiffness ratio (hardening) of the isolation system. They can be modeled either by expressing the hysteretic energy dissipation as an equivalent damping (by equating the area of the hysteresis loop to that of the ellipse representing viscous damping energy) or by directly including yielding elements at the pertinent positions of the bridge (such elements are available in most programs).

Shear Keys

Shear keys serve the purpose of preventing the displacement of the bridge deck in a certain direction and can be located at several positions in a bridge; a typical one is at the abutments for blocking the transverse movement of the deck. They can be either external as shown in Fig. 19 left (i.e., forming part of the seat) or as interior short cantilevers interlocking with corresponding grooves in the deck (Fig. 19 right); exterior shear keys are preferable because they are easy to inspect and repair. Shear keys might directly bear on the surrounding part of the deck, immediately blocking its movement, or be located at a selected distance, forming a local joint (see section “Joints” for modeling of joints).

Seismic Analysis of Concrete Bridges: Numerical Modeling, Fig. 19 Exterior and interior shear keys in bridges (Kappos et al. 2012)

Modeling of shear keys should be consistent with their design “philosophy,” i.e., whether the shear key is meant to remain essentially elastic for the entire range of seismic response of the bridge considered in design, or a “sacrificial” element whose capacity should be limited with a view to protecting other more critical and/or more difficult to repair components of the bridge; a popular design concept in California is that the capacity of the shear keys should not exceed or be close to the shear capacity of the piles (on which the abutment is supported). Eurocode 8-2 (CEN 2005a) vaguely specifies that the design actions for the seismic links (one type of which is shear keys) should be derived as capacity design effects, with the horizontal resistance of the bearings assumed equal to zero, without explaining how these effects should be derived (clearly one possibility could be to relate the strength of shear keys to that of piles, as mentioned previously).

The strength of shear keys can be derived from sophisticated models such as strut and tie ones or simplified ones, usually based on the shear friction concept. Bozorgzadeh et al. (2006) proposed the following relationship for the nominal capacity of a shear key:

$$V_n = \frac{\mu_f \cdot \cos \alpha + \sin \alpha}{1 - \mu_f \cdot \tan \beta} \cdot A_{vf} \cdot f_{su} \quad (15)$$

where μ_f is a kinematic friction coefficient, β is the angle of inclined face of the shear key (Fig. 19 left), α is the angle of kinking of the vertical bars with respect to the vertical axis (recommended value from test results 37°), and f_{su} is the (ultimate) tensile strength of the vertical reinforcement that has an area A_{vf} . Such models strongly depend on the friction coefficient that varies substantially depending on the detailing of the shear key; for sacrificial keys with smooth finishing of the concrete interface, $\mu_f = 0.36$ is recommended (Bozorgzadeh et al. 2006), but for properly detailed joints of adequate roughness, much higher values apply (up to 1.4 for keys monolithically cast with the abutment seat).

Having established a proper value for the shear key strength, the key can be modeled simply as a rigid-plastic spring (or “link”) with a

displacement capacity of around 100 mm or using more sophisticated multilinear constitutive laws with ascending and descending branches (see more details in Kappos et al. 2012). In linear, “code-type,” analysis, one usual option in the USA is to carry out two analyses, one with and one without the shear keys (essentially one assuming displacement is blocked in the pertinent direction and one with the deck allowed to displace freely).

Joints

Joints (also called *expansion joints* which is inappropriate when they are also designed for seismic actions) are required to accommodate (with negligible resistance and noise) movements of the deck due to:

- Thermal expansion/contraction
- Shrinkage and creep of concrete
- Earthquake-induced horizontal movement

There are several types of joints (compression seal, strip seal, finger plate, sliding plate, modular), each of them appropriate for up to a certain design movement of the bridge. In bridges designed for high seismic actions, the joint gap might result as quite substantial (over 200 mm). It is noted that current seismic codes like Eurocode 8-2 require the joint gap to satisfy

$$d_{ED} = d_E + d_G + \psi_2 d_T \quad (16)$$

where d_G is the long-term horizontal displacement due to permanent and quasi-permanent actions (posttensioning, shrinkage, and creep), d_T the displacement due to thermal actions ($\psi_2 = 0.5$ for road bridges), and d_E is the seismic displacement calculated as $\pm \eta \mu_d d_{Ee}$ where d_{Ee} is the displacement derived from the analysis for the seismic loading combination (with the design spectrum reduced by the behavior factor q), μ_d is the design ductility ($\mu_d = q$ in the common case that the fundamental period of the bridge $T \geq T_o = 1.25T_c$ where T_c is the corner period of the design spectrum) and η is the damping correction factor for the design spectrum ($\eta = 1$ for $\xi = 5\%$).

Seismic Analysis of Concrete Bridges: Numerical Modeling, Fig. 20 Pushover curves for the longitudinal direction of an overpass bridge (Kappos and Sextos 2009); “E” denotes the design earthquake level

When large movements ($d_{Ed} > 100$ mm) have to be accommodated, *modular* joints are used, wherein sealing elements and rail elements are coupled; in this case intermediate elements (rails), supporting elements, and linkage elements (e.g., folding trellis) causing equal gap widths are needed, and the total movement accommodated by the joint is the sum of the distances of the rails.

It is common practice in Europe to provide substantial joint gaps (as well as ample seat lengths) and make sure that the joints remain open during the design earthquake, without carrying out specific verifications for the case that the gap closes. In California, “dual” analysis is the recommended (by Caltrans) practice, wherein the bridge is analyzed assuming either free movement or full restraint at the “compression end” of the bridge (movement is always free at the “tension end” where the deck moves away from the abutment) and taking the most unfavorable response quantities from either set of analyses; clearly this is conservative and might result in increased costs. Another interesting difference in US and European practice is that *restrainers* (either cables or bolt linkages, the bolts passing through holes in the deck) are often used at the

joints of US (and New Zealand) bridges, with a view to preventing *unseating* during earthquakes stronger than the design one. In Europe this is seen as an option mainly in *retrofitting* of existing bridges with insufficient seating lengths.

Modeling of joints in seismic analysis is essential, since the bridge boundary conditions are drastically different when joints are open or closed. For instance, in the longitudinal direction of the bridge, there are at least two joints at the ends (over the seat-type abutments) that are essential for accommodating “non-seismic” displacements (d_G and d_T); when either of these joints closes during the earthquake, substantial forces are transferred to the abutment-backfill system (see section “[Abutments and Backfills](#)” and Fig. 20 later in this section), and the horizontal forces developed in the bridge-abutment-backfill system can be much higher than those developed when longitudinal movement was free.

Proper modeling of joints requires *nonlinear* analysis using the gap (or other special link) elements currently available in most software packages. This element is often combined in series with the spring (or link) elements modeling the bearings and/or shear keys at the abutment.

It is noted that although the gap element has an elastic behavior subsequent to gap closure, the analysis of the bridge is nonlinear, as the boundary conditions change during the analysis. The importance of capturing the effect of joint closure on the seismic behavior of a bridge can be seen in Fig. 20, where pushover curves are given for the longitudinal direction of a typical overpass (whose abutment system is shown in Fig. 12). Recall that two different soil conditions were studied; this has a noticeable effect on the initial stiffness of the bridge, but as soon as the longitudinal gap (120 mm in this case) closes, a drastic increase in both stiffness and strength is noticed, as the abutment-backfill system is now activated. The final failure of the bridge is estimated to take place during this second stage of the response (at a displacement of almost twice the gap length) and is attributed to unrecoverable damage to the soil behind the abutment (50 % loss in strength), while the piers are still well within their rotational capacity (35–49 %). A different failure mechanism (exceedance of available ductility of piers) would have been predicted had the end support been simulated as longitudinal restraint (as per the Caltrans simplified approach).

Bridge Analysis Methods

Methods of analysis can be classified as:

- Elastic (equivalent) static
- Elastic dynamic (response spectrum)
- Inelastic static (pushover)
- Inelastic dynamic (response history)

The basics of all these methods are presented in a series of articles in the encyclopedia and will not be repeated herein. Instead, some aspects of analysis (other than member modeling that was presented in section “[Modeling of Bridge Components](#)”) specific to concrete bridges will be briefly described, and the current trends in nonlinear static (pushover) analysis of bridges (not covered elsewhere here) will also be

presented. These will be followed by a case study involving application of different analysis method to an actual concrete bridge.

Code-Prescribed Analysis of Concrete Bridges

Among the important documents (codes-guidelines) for the *analysis* of concrete bridges are those regularly published by Caltrans (2013, latest version) and the ACI (2014, latest version) in the USA and Eurocode 8-2 (CEN 2005a) in Europe. Concrete bridges are the sole type covered in the ACI Report 341.2, while the Caltrans Criteria and Eurocode 8-2 also cover bridges made of other materials (steel and composite). For *retrofitting* of bridges a comprehensive document is the FHWA (2006) Manual. Some key aspects of these documents specific to the analysis of concrete bridges are discussed in the following. Other important sections relevant to the design of concrete bridges are those prescribing the procedures for resistance verification of reinforced concrete sections and the detailing of R/C members (piers, abutments, and retaining walls), which fall beyond the scope of this entry that focuses on modeling for structural analysis. Of course, calculation of R/C member strength and ductility (especially for piers) is essential for nonlinear analysis of concrete bridges; aspects of this issue are covered in the case study presented later in section “[Comparative Case Study](#).”

- All types of analysis are permitted for concrete bridges, the *equivalent static procedure* being subject to a number of limitations regarding the effect of higher modes; this type of analysis is usually suitable for the longitudinal direction of straight bridges, which is dominated by a single mode (that is often the fundamental mode of the bridge). Three versions of the method (Rigid Deck Model, Flexible Deck Model, Individual Pier Model) are prescribed by Eurocode 8-2 (see basic aspects of these methods in Vayas-Iliopoulos (2014)). The reference method in practical design is the (elastic) *dynamic response spectrum analysis*, while *nonlinear* methods are only used in practice for the verification of the design of

some important bridges that have initially been designed using response spectrum analysis. Nonlinear methods are much more common in the case of *assessment* of existing bridges. The FHWA (2006) Retrofit Manual provides sufficient guidance (especially with respect to estimating strength and deformation capacity) for the application of both the push-over and response-history analysis methods, which are covered more briefly in Eurocode 8-2; notably, assessment of existing bridges is not currently covered by the Eurocode package (it is one of the issues that will be added at the next stage of development).

- Application of elastic methods to bridges is the same as for other structures, but there are two aspects specific to concrete bridges that have to be properly addressed:
 - In most concrete bridges both prestressed and ordinary (non-prestressed) concrete are used, the former for the deck, the latter for the piers and abutments. The *damping* ratio ξ is different for these two materials (primarily due to the different degrees of cracking in each), i.e., 5 % for reinforced concrete and 2 % for prestressed concrete. In EC8-2 this is accounted for by considering the response spectrum for an equivalent damping ratio:

$$\xi_{\text{ef}} = \frac{\sum \xi_i E_{\text{di}}}{\sum E_{\text{di}}} \quad (17)$$

where E_{di} is the deformation energy induced in member i by the seismic action. This quantity is not a standard output of common structural analysis programs, and in order to avoid ad hoc spreadsheet calculations, designers often prefer to simply use an average value of 3.5 %. It is worth noting here that E_{di} is *not* the energy *dissipation* through yielding mechanisms, but rather refers to the pre-yield state; hence, it is not appropriate to consider a spectrum for $\xi = 5$ % on the basis that only reinforced concrete members yield and dissipate energy (prestressed concrete decks remain quasi-elastic as already mentioned in section “[Deck](#)”).

- The most important factor in reducing the elastic response spectrum to the design one (which is, in fact, an inelastic spectrum except when elastic response is foreseen for the design seismic action) is the force reduction factor, called *behavior factor* (q) in Eurocode 8 and *response modification factor* (R) in the US codes. Values for q for concrete bridges depend on whether the bridge is designed as ductile or “limited ductile.” For *ductile* concrete bridges with *vertical* piers (working in prevailing bending) $q = 3.5\lambda(\alpha_s)$, where $\lambda(\alpha_s) = 1.0$ for $(\alpha_s) \geq 3$ ($\alpha_s = L_s/h$ is the shear span ratio of the pier, where L_s is the distance from the plastic hinge to the point of zero moment and h is the depth of the cross section in the direction of flexure of the plastic hinge) and $\lambda(\alpha_s) = \sqrt[3]{(\alpha_s/3)}$ for $3 > (\alpha_s) \geq 1$. For ductile concrete bridges with piers consisting of *inclined* struts (e.g., V shaped), $q = 2.1\lambda(\alpha_s)$. For *limited ductile* concrete bridges, the corresponding values are 1.5 (vertical piers) and 1.2 (inclined struts). For abutments rigidly connected to the deck (integral bridges) $q = 1.5$, except in “locked-in” structures, i.e., bridge structures whose mass essentially follows the horizontal seismic motion of the ground (hence, they do not experience significant amplification of the horizontal ground acceleration), in which case $q = 1$. These values, as well as similar ones specified by the American Code (AASHTO 2010), are in many cases conservative. In a recent study evaluating the actual force reduction factors for existing bridges in Europe, Kappos et al. (2013) found that in all bridges studied the available q values were higher than those used for design in both the longitudinal and transverse directions. In fact, in many cases the code-specified values (in particular those of AASHTO for single-column bents) seem to significantly underestimate the actual energy dissipation capacity of concrete bridges. Seen from another perspective,

this is a clear indication that modern bridges possess adequate margins of safety and are able to withstand seismic actions that are often substantially higher than those used for their design. This high performance is due to their ductility, as well as their overstrength; previous studies that have ignored the latter led to unrealistically low estimation of q -factor values.

Nonlinear Static Analysis of Concrete Bridges

Interesting and useful work has been carried out in the last decade on nonlinear (inelastic) static, also known as pushover, analysis of bridges; nevertheless this is clearly less than that for buildings. A recent book presenting all available methods for pushover analysis of bridges is that by Kappos et al. (2012), which also includes a substantial number of case studies involving the comparative application of several methods. Due to space limitations, only one approach will be presented herein which, in the writer's opinion, combines sufficient accuracy with relatively limited effort and the possibility to be applied using available (commercial) software tools, with very limited need for additional spreadsheet calculations; in fact, software for "single-run" application of the method is currently at an advanced level of development. The method is usually referred to as *(multi-)modal pushover analysis (MPA)*; it was presented in a comprehensive form for buildings by Chopra and Goel (2002) and was extended to bridges by Paraskeva et al. (2006). The key idea is to perform multiple pushover analyses of the structure, one for each significant mode, and combine statistically the resulting displacements and rotations. The steps involved in the latest version of the method (Paraskeva and Kappos 2010), which includes a number of improvements, are summarized in the following.

Step 1: Compute the natural periods, T_n , and mode shapes, ϕ_n , for linearly elastic vibration of the structure.

Step 2: Carry out separate pushover analyses for force distribution $\mathbf{s}_n^* = \mathbf{m} \cdot \phi_n$ for each

significant mode of the bridge and construct the pushover curve (base shear V_{bn} vs. displacement u_{cn} of the "control" or "monitoring" point) for each mode; $\mathbf{s}_n^*$ are loading patterns; hence, the relative significance of each mode is not accounted for at this stage; this will be done at Step 5, through the target displacement for each modal pushover analysis. Gravity loads are applied before each MPA and $P-\Delta$ effects are included, if significant (e.g., in bridges with tall piers).

Step 3: The pushover curve must be idealized as a bilinear curve so that a yield point and ductility factor can be defined and subsequently used to appropriately reduce the elastic response spectra representing the seismic action considered for assessment. This idealization can be done in a number of ways, some more involved than others; it is suggested to do this once using the full pushover curve (i.e., analysis up to "failure" of the structure, defined by a drop in peak strength of about 20 %) and the equal energy absorption rule (equal areas under the actual and the bilinear curve). It is noted that the remaining steps of the methodology can be applied even if a different method for producing a bilinear curve is used.

Step 4: Several procedures are available (FEMA 1997; Chopra and Goel 2002; CEN 2004, all referring to buildings) for defining the earthquake displacement demand associated with each of the pushover curves derived in Step 3. Paraskeva et al. (2006) adopted the capacity and demand spectra procedure based on inelastic demand spectra (Fajfar 1999); hence, Step 4 consists in converting the idealized $V_{bn} - u_{cn}$ pushover curve of the multi-degree-of freedom (MDOF) system to a "capacity diagram" (Fig. 21). The base shear forces and the corresponding displacements in each pushover curve are converted to spectral acceleration (S_a) and spectral displacements (S_d), respectively, of an equivalent single-degree-of-freedom (SDOF) system, using the relationships (Chopra and Goel 2002):

Seismic Analysis of Concrete Bridges: Numerical Modeling, Fig. 21 Idealized pushover curve of the n th mode of the MDOF system and corresponding capacity curve for the n th mode of the equivalent inelastic SDOF system

$$S_a = \frac{V_{bn}}{M_n^*} \quad (18a)$$

$$S_d = \frac{u_{cn}}{\Gamma_n \cdot \phi_{cn}} \quad (18b)$$

wherein ϕ_{cn} is the value of ϕ_n at the control (or “monitoring”) point, $M_n^* = L_n \cdot \Gamma_n$ is the effective modal mass, with $L_n = \Phi_n^T \mathbf{m} \cdot \mathbf{1}$, $\Gamma_n = L_n/M_n$ is a mass participation factor, and $M_n = \Phi_n^T \mathbf{m} \cdot \Phi_n$ is the generalized mass, for the n th natural mode. For *inelastic* behavior, estimation of the displacement demand at the monitoring point is made with the aid of inelastic spectra.

Step 5: Since the displacement demand calculated in Step 4 (for each mode) refers to SDOF systems with periods equal to those of the corresponding modes, the next step is to correlate these displacements to those of the actual bridge. Hence, Step 5 consists in converting the displacement demand of the n th mode inelastic SDOF system to the peak displacement of the monitoring point, u_{cn} of the bridge, using Eq. 18b. The selection of this point is a critical issue for MPA of bridges, and as discussed by Paraskeva et al. (2006), several choices of monitoring point are acceptable as long as the derived pushover curve has a reasonable shape, but they do not

lead to equally good results as far as the final response quantities are concerned. For practical purposes, a good selection is the deck point above the most critical support (pier or abutment) of the bridge.

Step 6: In this step, a correction is made of the displacement of the monitoring point of the bridge, which was calculated at the previous step. The correction is necessary only for cases that significant inelasticity develops in the structure. If the structure remains elastic or close to the yield point, the MPA procedure suggested by Paraskeva et al. (2006) is used to estimate seismic demands for the bridge. The response displacements of the structure are evaluated by extracting from the database of the individual pushover analyses the values of the desired responses at which the displacement at the control point is equal to u_{cn} (see Eq. 18b). These displacements are then applied to derive a new vector Φ_n' , which is the deformed shape (affected by inelastic effects) of the bridge subjected to the given modal load pattern. The target displacement at the monitoring point for each pushover analysis is calculated again with the use of Φ_n' , solving Eq. 18b for u_{cn}' , and recalculated Γ_n using Φ_n' .

Step 7: The response quantities of interest (displacements, plastic hinge rotations, forces in the piers) are evaluated by extracting from

the database of the individual pushover analyses the values of the desired responses r_n , due to the combined effects of gravity and lateral loads for the analysis step at which the displacement at the control point is equal to u_{cn} (or u_{cn}').

Step 8: Steps 3–7 are repeated for as many modes as required for sufficient accuracy; there is little merit in adding modes whose participation factor is very low (say less than 1 %), and application of the method to a number of bridges shows that it is not necessary to assure that the considered modes contribute to 90 % of the total mass.

Step 9: The total value for any desired response quantity (and each level of earthquake intensity considered) can be determined by combining the peak “modal” responses r_{no} using an appropriate modal combination rule, e.g., SRSS or CQC. This simple procedure is used for both displacements and plastic hinge rotations, which are the main quantities commonly used for seismic assessment of bridges. If member forces (e.g., pier shears) have to be determined accurately, a more involved procedure of combining modal responses should be used, consisting in correcting the bending moments at member ends (whenever yield values were exceeded) on the basis of the relevant moment versus rotation ($M - \theta$) diagram and the value of the calculated plastic hinge rotation; this procedure blends well with the capabilities of currently available software.

Comparative Case Study

The overpass shown in Fig. 2 (some aspects of its modeling were discussed in section “[Modeling of Bridge Components](#)”) has three spans and total length equal to 100 m, typical in modern motorway construction. Piers have a cylindrical cross section, while the pier heights are 8 m and 10 m. The deck is monolithically connected to the piers, while it rests on its two abutments through elastomeric bearings; movement in both the longitudinal and transverse directions is initially allowed at the abutments, but transverse displacements are restrained whenever the 150 mm gap shown

at the bottom of Fig. 2 is closed. The Greek Seismic Code design spectrum (similar to that of EC8) scaled to a PGA of 0.16 g was used for seismic design. The design spectrum corresponded to ground category “B” (close to ground “C” in the final version of EC8 (CEN 2004)). The bridge was designed as a ductile structure (plastic hinges expected in the piers) for a behavior factor $q = 2.4$.

The bridge was analyzed applying a number of popular assessment procedures, i.e.:

- Modal analysis
- “Standard” pushover analysis (SPA) (first mode loading)
- Pushover analysis for a “uniform” loading pattern (as required by Eurocode 8 (CEN 2004) and by the ASCE Standard 41–06 (ASCE/SEI 2007))
- Modal pushover analysis (MPA) as proposed in Paraskeva et al. (2006)
- Improved modal pushover analysis as proposed by Paraskeva and Kappos (2010)
- Nonlinear response-history analysis (NRHA), for artificial records closely matching the demand spectrum (see Paraskeva et al. 2006)

All inelastic analyses were carried out using the SAP2000 software package (CSI 2011). Plastic hinging in the piers had to be modeled slightly differently in the NRHA and the pushover analysis, due to limitations of the software used. More specifically, nonlinear rotational spring elements were used in the finite element models used in NRHA, while the built-in beam hinge feature of SAP2000 was implemented in the models set up for pushover analysis. In both cases, though, the same moment versus rotation ($M - \theta$) relationship was used (i.e., bilinear with 2–6 % hardening, depending on the calculated ultimate moment), with input parameters defined from fiber analysis performed for each pier section, utilizing the in-house developed computer program RCCOLA-90.

Nonlinear Static Analysis

The dynamic characteristics of the bridge were determined using standard modal (eigenvalue)

Seismic Analysis of Concrete Bridges: Numerical Modeling, Fig. 22 Modal force distribution, location of the equivalent SDOF systems, and modal parameters for the main transverse modes of the overpass bridge

analysis. Figure 22 illustrates the first three transverse mode shapes of the overpass bridge, together with the corresponding participation factors and mass ratios, as well as the locations of alternative monitoring points for each mode. Consideration of the modes shown in Fig. 22 assures that more than 90 % of the total mass in the transverse direction is considered. For MPA, applying the modal load pattern of the n th mode in the transverse direction of the bridge, the corresponding pushover curve was constructed and then idealized as a bilinear curve (Fig. 21). As noted under Step 4 of the MPA procedure (see section “Nonlinear Static Analysis of Concrete Bridges”), the inelastic demand spectra method was used for defining the displacement demand for a given earthquake intensity.

Figure 23 illustrates the deck displacements of the bridge derived using pushover analysis for each mode independently, as well as the MPA procedure initially proposed in Paraskeva et al. (2006). If the structure remains elastic for the given earthquake intensity, both spectral displacement S_d and the product $\Gamma_n \cdot \Phi_n$ will be independent of the selection of the control (monitoring) point; this means that deck displacements are independent of the location of the monitoring point. On the contrary, it was found that deck displacements derived with respect to different control points, for *inelastic* behavior of the

structure, are not identical but rather the estimated deformed shape of the bridge depends on the monitoring point selected for drawing the pushover curve for each mode.

For inelastic behavior, it appears that the estimated values of u_{cn} are different not only because of the deviation of the elastic mode shape Φ_n from the actual deformed shape of the structure but also due to the fact that the spectral displacement S_d is dependent on the selection of monitoring point if the structure exhibits inelastic behavior (due to the bilinearization of the capacity curve). An improved target displacement of the monitoring point is calculated (from Eq. 18b) using Φ'_n , the actual deformed shape of the structure (see Fig. 23), while the spectral displacement remains the same. The response quantities of interest are evaluated by extracting from the “database” the values of the desired responses, r_n , for the analysis step at which the displacement at the control point is equal to u_{cn}' (the improved estimate of u_{cn} derived on the basis of Φ'_n).

Figure 24 illustrates the deck displacements of the overpass bridge, calculated from MPA using u_{cn}' as target displacement for each mode. It is noted that, due to the approximations involved in the capacity and demand spectra procedure, deck displacements derived with respect to different control points are not the same, but differences are significantly reduced and results are deemed

Seismic Analysis of Concrete Bridges: Numerical Modeling,

Seismic Analysis of Concrete Bridges: Numerical Modeling,

Fig. 25 Response to the design earthquake ($A_g = 0.16$ g) and to twice the design earthquake ($A_g = 0.32$ g) calculated from SPA, MPA, and NRHA: deck displacements of the overpass bridge

acceptable for all practical purposes. Paraskeva and Kappos (2010) also studied other bridges with different configurations and noted that the differences between deck displacements derived with respect to different control points, as well as the improvement in the prediction of deck displacements using the procedure described in section “Nonlinear Static Analysis of Concrete Bridges,” are more significant in bridges longer than the overpass of Fig. 2, especially if the increased length is combined with significant curvature in plan, which amplifies the complexity of its dynamic behavior and results in more significant contribution of the higher modes.

Reliability of Static Analysis Procedures

Results of the standard and modal pushover approaches were evaluated by comparing them with those from nonlinear response-history

analysis, the latter considered as the most rigorous procedure to estimate seismic demand. To this effect, a series of NRHAs was performed using five artificial records compatible with the design elastic spectrum. The Newmark $\gamma = 1/2$, $\beta = 1/4$ integration method was used, with time step $\Delta t = 0.0025$ s and a total of 10,000 steps (25 s of input). A uniform damping value of 5 % was assumed for all modes of vibration, while hysteretic damping was accounted for through the elastoplastic behavior of the structural members.

The displacements determined by the SPA and MPA procedures were checked against those from NRHA for increasing levels of earthquake excitation, as shown in Fig. 25. It is noted that the deck displacements shown in the figures as the NRHA case are the average of the peak displacements recorded in the structure during the five response-history analyses. In this study the

displacement demand was estimated independently in static and dynamic (response-history) inelastic analysis, whereas in some previous studies comparisons of displacement profiles were made assuming the same maximum displacement in both cases; the choice adopted here is deemed as more relevant for practical applications, as it permits an evaluation of all aspects of the proposed procedure (including the uncertainty in estimating displacement demand in pushover analysis).

As shown in Fig. 25, the MPA procedure predicts well (i.e., matches closely the values from the NRHA approach) the maximum transverse displacement. On the other hand, the SPA procedure underestimates the displacements of the deck at the location of the abutment A1 and the first pier of the bridge, compared to the more refined NRHA approach. This is not surprising if one notes the differences between the first two mode shapes in the transverse direction (Fig. 22), which are strongly affected by torsion (they contribute more than 90 % of the torsional response, as well as over 90 % of the transverse response of the bridge) due to the unrestrained transverse displacement at the abutments (until the 150 mm gap closes), combined with the different stiffness of the two piers caused by their different height. What is essentially achieved by the MPA is the combination of these first two modes (the 3rd transverse mode is not important in this particular bridge), each of which dominates the response in the region of the corresponding abutment. In the case of applying ground motions with twice the design earthquake intensity (also shown in Fig. 25), where the structure enters deeper into the inelastic range and higher mode contributions become more significant (without substantial alteration of the mode shapes), it is noted that the displacement profile derived by the MPA method tends to match that obtained by the NRHA, whereas SPA predictions remain poor. Note that, regardless of earthquake intensity, the uniform loading pattern (also shown in Fig. 25) fails to capture the increased displacements toward the abutments; nevertheless its overall prediction of the displacement profile could be

deemed better than that resulting from using a single modal load pattern.

Additional case studies reported by Paraskeva and Kappos (2010) confirm that SPA predicts well (i.e., matches closely the values from the NRHA approach) the maximum transverse displacement, when applied to bridges of regular configuration, where the higher mode contribution is not significant. In such cases the improvement of the displacements derived by the MPA procedure is not significant even for high levels of earthquake excitation.

Summary and Concluding Remarks

It is clear that today the bridge engineer has at his/her disposal a set of powerful analysis tools that can be used for the seismic design or assessment of any bridge type. The potential of these tools, when properly utilized, was revealed by their success in predicting the response of bridges tested under high levels of earthquake actions that caused substantial amounts of inelasticity; an example was presented in section “[Comparative Case Study](#).” The information on bridge modeling presented in section “[Modeling of Bridge Components](#)” offers to researchers and designers the necessary information regarding the available models for the various parts of the bridge (deck, bearings and shear keys, isolation and energy dissipation devices, piers, foundation members), as well as tools for modeling the dynamic interaction between piers, foundation, and soil, as well as the abutment-embankment-superstructure system. It also provides information on important parameters that help ensuring that inelastic analysis of bridge earthquake response is conducted properly. It has to be emphasized in this respect that the power and versatility of the analysis tools also makes the results particularly sensitive to improper application.

Special emphasis was given to modeling of piers (section “[Piers and Their Foundations](#)”), as these members are both the ones wherein energy dissipation through plastic hinging is intended to

occur (unless a seismic isolation system is used) and those whose inelastic response is relatively easier to model in inelastic analysis (compared, for instance, to the abutment-backfill system or some foundation types or, indeed, some types of joints). Having said this, it is also clear from the material presented in this entry that proper modeling of the other components of the bridge, even those that are typically assumed to remain elastic during the seismic excitation (such as prestressed concrete decks), is also important, since, through their stiffness characteristics, they affect the dynamic characteristics of the bridge and the way seismic actions are transferred to the dissipating zones. Of great importance is also the modeling of the various connections in the bridge system, i.e., those between piers and deck, abutments and deck, and, in the common case (especially in the transverse direction) that the movement of the deck is restrained at the location of the abutment, the proper modeling of the response of the abutment-backfill system. As noted in section “[Abutments and Backfills](#),” in a practical context and when the main objective of the analysis is the response of the bridge itself (rather than that of the surrounding ground), the recommended solution is to carry out an independent analysis of the abutment-embankment system, determine its resistance curves (in all relevant directions), and use them to describe the nonlinear response of the equivalent springs to which the bridge model will be connected. If such an analysis cannot be afforded, the properties of these springs can be defined on the basis of simplified guidelines from the literature. For pier-foundation-soil interaction, the existing literature is more mature and often it is not necessary to carry out separate analysis of the system to derive the nonlinear properties of the soil-foundation dynamic impedance to be introduced in the bridge model, especially when surface foundations are used; in these cases information from the literature can be used to account approximately for the interaction with the surrounding ground.

Regarding the feasibility and reliability of different methods used for the analysis of concrete

bridges, these depend primarily on the configuration of the bridge analyzed. As a rule, the longitudinal direction of the bridge is the easier one to analyze, and even simple, equivalent static elastic methods can lead to a reasonable design. In most other cases dynamic analysis is required to properly capture the higher mode effects that are important, especially in the areas close to the abutments. When the expected plastic mechanism does not involve more-or-less uniform yielding in the energy dissipation zones of the bridge (this is the case of irregular pier configurations), inelastic analysis is strongly recommended for verifying the design initially carried out using standard modal (response spectrum) analysis. Nonlinear analysis is clearly the preferred choice in the case of assessing existing bridges not properly detailed for seismic performance; for such bridges the simplest choice is standard pushover analysis, but whenever more than one mode affects the response (this is very often the case in the transverse direction of the bridge) more sophisticated tools like the multimodal pushover method presented in sections “[Nonlinear Static Analysis of Concrete Bridges](#)” and “[Comparative Case Study](#)” have to be used. The use of such analytical tools is expected to increase when the software required for applying them in a single run becomes widely available.

Introduction

Masonry building construction encompasses the large inventory of structures built worldwide solely or partially of individually laid masonry units bonded or not together with some type of mortar, possibly with the incorporation of reinforcement; depending on the constituent materials, stacking, and bonding techniques, different technologies are adopted for building the masonry elements that comprise the entire building; thus, materials and techniques adopted worldwide vary with local customs, socioeconomic conditions, and available technology. A comprehensive continuously updated description of the different materials and technologies of construction around the world is given in the World Housing Encyclopedia (EERI/IAEE).

Because of their widespread use, masonry structures house not only the population but also important social and economic operations such as hospitals and schools, high congregation areas, business, small to medium industry, and civil

administration (UNIDO 1983); furthermore, being historically one of the earliest forms of construction, they also house the people's cultural heritage, most often being such by themselves (Figs. 1, 2, 3, and 4).

Due to their geographic spread, masonry structures are exposed to different levels of seismic hazard; in fact, a significant portion of cultural heritage structures are located in earthquake prone-areas of Europe, Asia, and South America. Recent devastating earthquakes (e.g., in New Zealand, Italy, Chile, India, Pakistan, and elsewhere) have shown that existing masonry structures are quite vulnerable to seismic actions, as also recorded in many seismic damage reconnaissance reports published after major earthquakes (e.g., among others, Hughes et al. 1990; Rossetto et al. 2009; DesRoches and Comerio 2011).

As a consequence of this fact, social and economic requirements for human safety and operability as well as the need for preservation of cultural heritage require more and more often that these structures be analyzed for seismic actions, in order to be designed (new construction), or their seismic vulnerability can be assessed and evaluated (existing construction) for the purpose of repair, rehabilitation, and/or strengthening to current seismic standards. The seismic performance assessment of existing masonry buildings also follows performance-based design (PBD) and analysis procedures, similar to other types of structures (e.g., concrete and steel buildings): hence, in the design of new construction, normative regulations, practices, and experience of good seismic performance have been encompassed (e.g., EC6 2005 for gravity load design and EC8 2004 for seismic design). On the other hand, codes and guidelines are being drafted for the assessment and retrofit of existing masonry buildings (e.g., FEMA-356 2000) or for cultural heritage structures (Moro 2007; ICOMOS; ISCARSAH).

Compared to the more recently evolved types of construction like steel and reinforced concrete, however, masonry buildings have certain inherent idiosyncrasies, which their modeling for seismic analysis should account for:

Seismic Analysis of Masonry Buildings: Numerical Modeling, Fig. 1 The stone masonry castle of Mycenae, Peloponnese, Greece, 2nd millennium BC (Source <http://en.wikipedia.org/wiki/Mycenae>)

Seismic Analysis of Masonry Buildings: Numerical Modeling, Fig. 3 The Alcantara bridge (104 AD), Spain (Source: http://en.wikipedia.org/wiki/Roman_bridge)

Seismic Analysis of Masonry Buildings: Numerical Modeling, Fig. 2 The Byzantine church of Hagia Sophia (360 AD), Istanbul, Turkey

Seismic Analysis of Masonry Buildings: Numerical Modeling, Fig. 4 The Aaos river bridge (eighteenth century), Hepirus, Greece

- (i) Masonry buildings are both non-engineered, namely, structures built with traditional means and experience, and engineered, namely, structures designed and constructed following engineering principles and, more recently, code regulations (e.g., EC6 2005; EC8 2004). In fact, earlier engineered masonry buildings have been designed for gravity loads only; only some types of recent masonry construction, following the evolution of seismic regulations, have also been designed for earthquake (IAEE 2008;

ASCE 2013; EC6 2005). In addition to the possible lack of proper design, they are also characterized by the usual problems in the load-bearing system similar to other structures, such as: irregularities in plan and/or elevation, improper foundation conditions, a history of (possibly undocumented) modifications in plan and elevation, and the decay of the material properties under environmental exposure.

- (ii) Depending on the prevailing socioeconomic conditions, masonry buildings are and have

Seismic Analysis of Masonry Buildings: Numerical Modeling, Fig. 5 Residential masonry buildings in Greece, built in the nineteenth and early twentieth century, reflecting different levels of socioeconomic status

been constructed using a variety of locally available technologies and materials (Fig. 5). Often, currently acceptable levels of quality control and supervision were not enforced. New masonry buildings in developed countries may use units manufactured industrially and with quality control; this is not the case for existing buildings in all countries or new masonry construction in underdeveloped countries (see typical examples offered in the World Housing Encyclopedia, [EERI/IAEE](#)).

- (iii) Masonry, unless suitably reinforced or confined, as in the case of new construction, cracks and fails in a brittle manner. Seismic analysis methods for existing or historical unreinforced masonry buildings need to take this fact into account.
- (iv) Masonry buildings suffer from structural inadequacies in the load-bearing system inherent in this type of construction, such as: the presence of diaphragms which are

poorly connected to the masonry for lateral load transfer, the relatively high flexibility of the floor diaphragms, and the way the masonry wall elements are constructed and tied together through the thickness and/or at their intersections. Seismic analysis modeling techniques should not overlook these particularities, if the analysis results are to be reliable.

Depending therefore on the problem at hand, reliable modeling for seismic analysis of masonry structures will have to account of these building characteristics, in order to reliably predict the damages expected and to identify the methods and extent of intervention required for strengthening these structures. Following a brief review of masonry building characteristics, the methods and limitations of different methodologies adopted for the seismic analysis of masonry construction are subsequently considered.

Modeling Techniques for Seismic Analysis of Masonry Buildings: Classification and Definitions

Masonry Materials Used

According to the type of masonry units employed, masonry is classified as stone masonry (Fig. 5), industrially manufactured clay brick (solid, hollow), site-produced mud brick or plinth (also known as adobe masonry), or industrially manufactured hollow or solid concrete masonry units (CMU) in fully, partially grouted, or ungrouted construction. Other industrially manufactured types of block are also used worldwide such as lightweight concrete, cinder, fly ash, or autoclaved concrete, among others. Depending on the type of construction, reinforcement is also used to enhance the bearing capacity of masonry elements and to provide ductility to the structure. Another construction system (covered by modern codes, e.g., EC6 2005) is that of confined masonry: horizontal and vertical reinforced concrete elements are provided, at distances depending on the dimensions of the building and on the seismicity of the region. The ties, constructed during the construction of the masonry, function as linear tensioned members.

They assist masonry in taking shear and bending (in and out of plane) while they also contribute to the confinement of plain masonry, thus enhancing the ductility of the system.

In cultural heritage buildings in Europe and elsewhere, most frequent construction types of stone masonry are double-leaf masonry, made of two leaves, either independent or connected between them with sporadic header stones (Fig. 6), and three-leaf masonry, made of two independent leaves, with the space between them being filled with a more or less loose material of poor mechanical properties. Other types of masonry, like cavity masonry or timber reinforced one, are also quite frequent in historic structures.

Finally, the material that bonds the masonry units together may be none (also called dry construction), mud, or different types of mortar such as lime, lime–pozzolan, lime mortar reinforced with animal hair, or, in case of modern masonry construction, cement or lime–cement.

Load-Bearing Function of the Masonry

The type of load path of the vertical and transverse loads down to the foundation defines two basic types of masonry:

Seismic Analysis of Masonry Buildings: Numerical Modeling, Fig. 6 Unreinforced masonry construction technologies. (a) Dry masonry construction (Tiryns,

Argos, -Peloponnese, thirteenth to fourteenth century BC). (b) Double-leaf masonry wall. (c) Three-leaf rubble stone masonry. (d) Cavity wall (Van, Turkey)

- (i) **Load-bearing (LB) masonry**, bearing all the gravity and lateral loads from floors and roof to the foundation. Thus, the masonry elements themselves are responsible to provide overall lateral stability and to transfer the seismic inertia loads under in-plane and out-of-plane actions, down to the foundation, through combined flexural, axial, shear, or rigid body rocking mechanisms. Seismic analysis of this type of masonry involves adequate modeling of the entire load-bearing structural system response at the individual element level, including the diaphragms and the foundation, accounting for both in-plane and out-of-plane response, as discussed in the next section. As a special case of LB masonry construction, masonry arches are constructed with keystone elements at the apex, in order to provide the path of the line of thrust to the foundation.
- (ii) **Non-load-bearing (NLB) masonry**, in which the bearing function is provided by a structural skeleton made of other structural materials such as steel and timber or reinforced concrete (RC). Such is the case of the widely adopted masonry panel infilled RC building construction, a form of confined masonry, whose modeling is covered in section “[Modeling of NLBM Infilled Frame Buildings for Seismic Analysis.](#)”

If anything else, NLBM infill panels have to support with adequate resistance capacity and in a stable manner their own inertia forces as these are materialized at the building elevation relative to ground in which they are supported. Furthermore, through the deformation compatibility between the infill and the confining frame structure, they are forced to resist seismic load through a friction contact separation mechanism with the frame under lateral load response. Therefore, unless specifically isolated by adequate details from the bearing frame (over the entire lateral inelastic deformation expected), NLBM panels are seismically bearing, and consequently, even NLBM elements need to be included in seismic analysis of the entire building in which they are constructed.

Because of this contact mechanism, practical seismic analysis of this type of masonry construction involves macromodeling using axial load-bearing struts, as briefly discussed in section “[Modeling of NLBM Infilled Frame Buildings for Seismic Analysis.](#)”

Masonry Wall Construction Types and Resisting Mechanisms

Masonry walls, whether LBM or NLBM, range from single-leaf or multiple-leaf walls (Fig. 6) with interior cavities among the leaves, which are either void (e.g., the common double-leaf walls with space for sliding window frames) or are filled with rubble (typical for old masonry buildings, cultural heritage buildings included) or concrete (in modern masonry construction of reinforced cavity walls according to EC6 2005). Multiple-leaf walls may be tied to each other in modern construction (e.g., modern veneer brick masonry walls) or, as often the case in existing structures, they are untied.

The laying of the masonry units varies according to the local techniques, the material, and the production form of the unit. Industrial units are laid in courses (use of header courses or random laying construction and keystones at the intersections) and the provision of collar joints filled with mortar (and possibly steel) and/or the inclusion of bond beam elements. The vertical elements are traditionally built on a stone or brick or concrete footings, on which they rest or are tied to with reinforcement. Often, interior walls are in fact lighter construction partitions of brick or wood not tied to the load-bearing system, or the wall intersections were poorly connected.

Irrespective of material and load-bearing type, masonry is classified according to its resisting mechanisms as unreinforced masonry, reinforced masonry (prestressing possibly included), and confined masonry, depending on whether reinforcement or additional confining elements within the masonry are used. The use of each type in new constructions in seismic regions depends on the seismicity of the region, on the number of stories, etc. (see, e.g., EC8 2004).

- (i) **Unreinforced masonry (URM)**, namely, masonry without any or very small amounts

Seismic Analysis of Masonry Buildings: Numerical Modeling, Fig. 7 Reinforced masonry construction technology and detail. (a) Modern CMU reinforced masonry residential building (Source: [http://en.](http://en.wikipedia.org/wiki/Masonry_structure)

[wikipedia.org/wiki/Masonry_structure](http://en.wikipedia.org/wiki/Masonry_structure)). (b) Reinforced masonry construction detail using clay bricks with improved thermal insulation properties

of reinforcement included and without any additional confining members within the masonry body. This form of masonry construction is the most frequently encountered type of construction in existing or historical buildings and is associated with the largest amount of modeling problems, due to the variety of techniques and materials adopted and the variability of their properties. Seismic analysis methods for URM buildings need to account for the mechanical characteristics of the material, obtained from in situ evaluation using flat jacks or through testing (e.g., Clough et al. 1979; Magenes et al. 2008; Vintzileou and Miltiadou-Fezans 2008; Ruiz-Garcia and Negrete 2009; and the TCCMaR test series, Kingsley 1994); furthermore, modeling should account for the brittle nature of its response. Only elastic methods of analysis are therefore meaningful in their seismic performance assessment, whereas a low behavior factor (~ 1.50) is applicable for evaluation of the seismic forces.

- (ii) **Reinforced masonry (RM)** is masonry with horizontal reinforcement in mortar bed joints and vertical reinforcement positioned in a cavity or in holes of the vertically perforated masonry units or in grooves between adjacent blocks (Fig. 7a, b).

In modern construction, reinforcement comprises steel reinforcing in the form of bars, trusses or cut wire mesh, dovetails,

and other special shaped proprietary ties, placed vertically and horizontally. Other reinforcing materials include prestressing strands (prestressed masonry) and polymers, used for external strengthening existing masonry. In addition to steel reinforcement used in modern construction, timber elements have traditionally been used in historical masonry structures and are still used in new buildings constructed in seismic regions in the developing world, with very good seismic performance characteristics (also called timber-laced buildings, Figs. 8 and 9).

Generally, reinforcement serves to connect the leaves of the masonry wall, to allow for uniform distribution of vertical loads at floors and roof levels, to act as shear and flexural reinforcement for in-plane and out-of-plane seismic load transfer, and also to provide ductility, when reinforcement yielding precedes brittle failure of the masonry; therefore, its beneficial role should be included in seismic analysis; furthermore, for new construction, when ductility is enforced by design, both elastic and inelastic methods of analysis are meaningful in seismic performance assessment, with a suitable response reduction coefficient applied in the expected seismic loads; in this context, behavior factors up to 3.0, comparable to RC wall construction, can be used in modern RM building design (EC6 2005).

Seismic Analysis of Masonry Buildings: Numerical Modeling, Fig. 9 Bhatar construction: traditional unreinforced load-bearing timber-laced masonry structure in Pakistan in modern construction (Source: <http://www.holcimfoundation.org/Projects/advocacy-of-traditional-earthquake-resistant-construction-north>)

Seismic Analysis of Masonry Buildings: Numerical Modeling, Fig. 10 Model of the Gaiola pombalina masonry confinement with timber, developed in Lisbon after the 1755 earthquake ([http://en.wikipedia.org/wiki/Gaiola_\(construction\)](http://en.wikipedia.org/wiki/Gaiola_(construction)))

- (iii) **Confined masonry (CM)** is masonry which encompasses during construction horizontal and/or vertical confining RC or RM elements, monolithically bonded into the masonry structure (e.g., RC lintel beams and pilasters). In fact, modern clay brick walls in seismic regions make use of such horizontal and vertical RC elements. In the case of RC confining elements, similar modeling conventions for seismic analysis are adopted as for RM buildings, using however higher seismic forces; in this case, a behavior factor of 2.0 is adopted in EC8 (2004).

A special form of URM and LBM construction originating in older (historic) buildings (a well-known case being the Pombalinas, constructed during the rebuilding of Lisbon following the devastation of the city on 1755) and still adopted in less developed countries (e.g., the *dhajji* in Pakistan) makes use of timber reinforcing elements in the form of tension–compression braces; they are built within the masonry walls at the floor levels or between floors, in order to confine the masonry infilling the voids (Fig. 10), thereby enhancing its in-plane shear resistance and providing damping under seismic response. This type of LBM construction is also behaving as CM and partially RM, due to the load-carrying mechanism provided by the timber elements and

the in-plane stabilization and stiffening role provided by the masonry infill, confined in turn by the timber structure; seismic modeling of such systems follows the macromodel approach (see section “[FE Modeling of LBM Structures for Seismic Analysis](#)”), whereby the confining timber elements are included in the model together with the masonry and are verified accordingly.

Seismic Analysis Methods of Masonry Buildings

Depending on the problem at hand, both linear and nonlinear analysis methods, as also employed for seismic analysis of RC and steel buildings, are being applied to LBM buildings according to the limit state objective of the verification and the ductility capacity of the masonry elements (if any).

Linear Elastic Analyses

For serviceability limit state (cracking, service load deformation) verifications, linear analysis methods are adequate, up to the onset of cracking of the masonry. The use of linear elastic analysis for the ultimate limit state (strength) design verification of URM buildings under seismic load combinations provides meaningful verification results only under seismic load levels obtained using a response reduction coefficient equal to 1.0; for the design of new RM buildings, it is possible to use linear elastic methods with higher behavior factors (up to 3.0), due to the inherent ductility capacity of the masonry. It should be noted, however, that in case of historic buildings, lower seismic actions than those prescribed by modern codes are frequently adopted. Actually, the application of the requirements of current codes may lead to invasive interventions that are against the internationally accepted charters for the preservation of the built cultural heritage (e.g., [ICOMOS](#); [ISCARSAH](#)).

Linear elastic analysis methods can also be adopted for ultimate limit state verifications of URM buildings, provided the structure does not have excessive irregularities ([EC6 2005](#)) and lacks significant torsional effects, thereby

exhibiting clearly separated orthogonal modes of vibration. Linear elastic modeling neglects cracking of the masonry elements and its influence in the kinematics and the redistribution of forces. Even if cracking is neglected, however, linear elastic models provide useful information about the structure and the model adopted since: (i) they give an indication of the areas of increased tensile or compressive stress in the masonry, which potentially need to be strengthened or rehabilitated; (ii) they can be easily compared with a visual or in situ measurement of cracking and stresses in the masonry, thus allowing to verify the reliability of the model and the reasons for the existing condition of the structure; and (iii) possible interacting factors of overstress can be established (e.g., earthquake following a long-term preexisting foundation settlement).

Static and Modal Elastic Analyses

Linear elastic analysis includes both equivalent static and modal analysis:

- (i) Static analysis can be used in buildings in which higher modes are not dominant in the response, the building is orthogonal in plan, and it does not exhibit major irregularities: two different lateral load distributions with height should be considered, representative of different modes of lateral deformation, namely, (a) triangular distribution and (b) uniform distribution. In the case of micromodels (see section “[FE Modeling of LBM Structures for Seismic Analysis](#)”), possible refinements on the linear elastic model can be considered through local modification of the finite element (FE) stiffness characteristics in order to account for cracking of the masonry, whether such is predicted from an elastic analysis or it is obtained from field inspection of the condition of the structure.
- (ii) Modal analyses, when used, should include all the modes with a modal mass that is greater than 5 % of the total mass of the building and enough modes whose modal masses sum to at least 75 % of the total building mass.

For the evaluation of the modal response characteristics – deformations and internal forces – using macromodels (see section “[FE Modeling of LBM Structures for Seismic Analysis](#)”), the square root of the sum of squares combination rule of modal quantities can be used if the modes differ with each other by as much as 90 %, or, better, using the complete quadratic combination rule, giving accurate maxima for closely coupled mode combinations. For seismic modal analyses using micromodels (e.g., shell finite elements), the peak response characteristics (deformations and internal stresses) $E_{\max}$ should be evaluated following:

$$E_{\max} = \max_t \left\{ \sum_{j=1}^n E_j(t) \right\} \quad (1)$$

where $E_j(t)$ is the time history of the corresponding parameter due to response in the j th eigenmode.

Inelastic Analyses

In currently accepted methodologies for the assessment of existing LBM buildings (both RM or URM) in the context of PBD, nonlinear static analysis methods and corresponding modeling conventions are employed with different levels of modeling detail, depending on whether cracking, post-ultimate, and cyclic hysteretic characteristics are included in the model (Fig. 11). The purpose of these methodologies is to evaluate the inelastic lateral load deformation

of the building, taking into account the actual inelastic characteristics of the elements, brittle or ductile; evaluation of this capacity curve yields the expected target deformation demands, under different seismic excitation levels (performance levels), at which point the onset, distribution, and extent of structural damages are obtained and compared to code damage levels (FEMA-356 2000), either in terms of element resistance (brittle element response) or in terms of inelastic deformations (ductile element response). For the evaluation of these generalized force–deformation characteristics, different failure mechanisms – accounting also for out-of-plane effects – can be considered, and the weakest governing mechanism should be adopted as governing the failure response.

Modeling of LBM Buildings for Seismic Analysis

The primary load-bearing elements of LBM construction are the vertical load-supporting elements, namely, the floor and roof structure, as well as the perimeter and interior bearing masonry walls. All these elements carry the vertical loads (including self-weight) and the lateral forces to the foundation. Secondary elements, not part of the lateral resisting system (such as light partitions), are not included in the model as earthquake resisting elements. Only their self-weight alone is taken into account in analysis.

Seismic Analysis of Masonry Buildings: Numerical Modeling, Fig. 11 Inelastic analysis constitutive models of masonry building elements for in-plane only action (bending or shear). (a) Simplified. (b) Refined

Floor and Roof Elements and Diaphragmatic Action

Floor structures and the roof structure transfer the vertical loads and in-plane inertia seismic loads to the rest of the bearing elements. While in modern masonry buildings floor elements are typically stiff RC diaphragms, in typical existing or historical masonry construction, light wooden floors on wood or steel purlins have been used traditionally. Brick or stone masonry vaults are also typical in the lower story of several historic structural systems; other variants include arched brick constructions between joists or two-way Zoellner diaphragms made of brick infilled voids. Purlins usually span one way and are simply resting or encased in the bearing walls at each end. A peculiarity of masonry buildings is that masses are not concentrated at floor levels; they are distributed over the height of the building.

Unlike modern construction concrete slabs which provide diaphragmatic action that distributes the inertia loads in plan and tie all the vertical masonry elements at the floor level, existing masonry structures were constructed with flexible diaphragms which deform in plane and operate differently during the earthquake (Fig. 12a). Therefore, the presence or absence of diaphragmatic action and the way the diaphragm is tied to the vertical elements are two important aspects to consider in seismic modeling, since the diaphragm stiffness will affect both the dynamic characteristics of the masonry building and the transfer of forces among the stiff vertical wall elements.

Along the same context, the function of the diaphragm (one-way flexible or two-way stiff action) shall also define the distribution of the floor plan masses to the walls: one-way joist diaphragms will only distribute inertia reaction loads across the walls at which their wooden joists are infamed, making the usual uniform mass distribution assumption in the building model, namely, a lumped rotational/translational mass at the center of mass, incorrect.

In addition to load distribution, failure of the diaphragm is also important to model: apart from failure of arch-supported diaphragms that tend to be sensitive to relative in-plane deformations of

the supporting walls, failure or collapse of flexible diaphragms takes the form of failure (usually pullout) of the diaphragm-to-wall connection, due to inertia force transfer or excessive out-of-plane deformation of the wall and loss of support of the timber elements to the wall. This type of behavior depends mostly on the vertical support system of the diaphragm and the detailing of the connections, which all need to be part of the building model (see, e.g., Vintzileou et al. 2007, for a description of the system used in the traditional masonry structures in Lefkada, Greece).

Seismic Load-Bearing (Primary) Vertical Elements

The primary lateral load-bearing elements of LBM buildings are the perimeter and interior bearing walls, which are typically perforated with openings, forming wall elements, spandrel beams (also arched lintel beams), and pilasters (Fig. 12b). The in-plane lateral load transfer of the wall elements depends on their aspect ratio (the height to width ratio): walls with relatively longer width compared to the element height (height to width ratio less than 2–3) tend after initial cracking to transfer the lateral force to the lower level directly through an inclined strut (including also the vertical load), whose horizontal component equals the lateral load; more slender walls or multiple wall elements (wallets) created in a wall with openings may opt for a more flexure-dominated behavior (similar considerations apply also to the horizontal spandrel beams between openings), while failure of these elements is brittle.

Since the walls are the primary lateral load resisting elements, their distribution in plan and their stiffness (namely, geometric size and percentage of opening area) determine the eccentricity between the center of application of the floor inertia forces (the center of mass for stiff diaphragms) and the center of rigidity of the building in plan. Consequently, irregularities that may arise in plan and also in elevation due to the wall distribution and geometry will influence the distribution of the lateral loads among the different resisting elements, something which is crucial to model in seismic analysis. It should

Seismic Analysis of Masonry Buildings: Numerical Modeling, Fig. 12 Good practices in the seismic analysis of masonry buildings. (a) Contributions of the seismic forces to the masonry façade in a typical URM building

through diaphragmatic action (where this exists). (b) Contributions of the three-dimensional analysis to the in-plane and out-of-plane actions on the facades and to the corner element forces

further be overemphasized that these structural characteristics are dependent on the intensity of the earthquake, since masonry (like concrete) cracks in tension or softens under extreme compression stresses, and therefore the relative stiffness of the bearing elements changes beyond

what has been assumed in an elastic analysis, redistributing forces as well as increasing the lateral deformation demands during the an earthquake. The analysis sophistication therefore and the modeling capabilities should reflect the level of response prediction.

In-plane response failure of the walls or other structural elements (where present) will take place due to inadequate resistance or excessive interstory drift. Masonry element failure includes wall pier, pilaster, or spandrel beam failure under in-plane actions. Depending on the aspect ratio of these elements and the existence of diaphragmatic action, failure of the wall elements affects individual masonry elements and will jeopardize the entire vertical load path to the lower floors, the building dynamic characteristics, as well as the redistribution of forces in and out of plane. Element failure takes the following forms:

- (i) Flexure-dominated failure including cracking and/or rocking of the wall, compressive toe failure of the wall
- (ii) Shear failure in plan, including sliding at mortar bed joints, diagonal cracking or diagonal crushing of the wall between the cracks
- (iii) Entire wall movement
- (iv) Apart from these in-plane response failure modes, walls may also fail under concurrent in-plane and out-of-plane action. In this case failure is closely associated with the existence or not of adequate diaphragmatic action and a suitable tensile diaphragm connection to the façade walls that will mobilize the entire building façade from the footing line (below grade) to the roof (Fig. 12a). Special cases of out-of-plane buckling failure under in-plane compressive action are also included in this combined failure mode, primarily for slender wall elements though, e.g., unsupported multiple-leaf walls.
- (v) Failure under combined biaxial effects (combined axial load) characterizes the corner walls and pilasters, due to the three-dimensional nature of the building response. Bidirectional rocking of the building (Fig. 12b) induces axial loads that are considerably higher than uniaxial predictions, together with biaxial bending and shear forces. In this case, a three-dimensional model of the building is needed to predict such overstress in the corners, with the results of plane analyses only being unconservative.

Secondary Elements

Such elements are typically the interior masonry (or other) column elements that support the diaphragm or narrow, slender elements on the façade that function as columns. The failure of these elements does not alter significantly the response of the building, and therefore, they are ignored in the seismic analysis model. However, their ability to bear vertical loads under the seismic deformation of the building should still be verified.

Foundation

The foundation of the masonry walls is not necessarily responding as rigid and non-deforming, as typically assumed in seismic modeling. Foundations may settle in the long term under the weight of the walls, inducing tensile cracks in the building that change the distribution of forces and the way the vertical elements respond (rocking rather than flexing). Furthermore, due to the lack of reinforcement, contact type of connection develops between the URM footing, the masonry wall, and the soil, with possible uplift and rocking under tensile or rocking response. These mechanisms should be captured in the seismic model, if the vertical and lateral loads are such as to allow for this kind of motion. Consequently, if preliminary analyses indicate this to be the case, the soil resistance to the footing stresses should be modeled using an elastic but tensionless type of behavior (e.g., a Winkler model with uplift), in order to obtain the proper footing flexibility as is the case in situ. An in situ geotechnical study and adequate knowledge of the foundation shall provide the soil constitutive characteristics and the foundation conditions (e.g., the possible existence of a well or a septic tank near the footing).

Principle Modeling Requirements for Seismic Analysis of LBM Buildings

In summary, the building seismic model used should identify the basic force transfer mechanisms of the structural system, irrespective of the method of analysis used:

- (a) *Plane or three-dimensional model.* Plane frames are often used as an approximation for modeling the building. It is important to

note that the proper idealization of seismic behavior is through modeling of the three-dimensional response. Two-dimensional models are unable to monitor the three-dimensional response of the entire structure; consequently their use will not predict the spatial response effects, namely, (i) the simultaneous action of seismic axial forces and biaxial bending effects in the corner piers, (ii) the corner element vertical deformation compatibility under concurrent actions in the two orthogonal directions, (iii) the influence of out-of-plane bending in the resistance of in-plane actions of the vertical elements, and (iv) the possible in plan torsional effects which will enter into the response in the case of a relatively rigid diaphragm and eccentric distributions of the mass (e.g., an opening) or the stiffness (e.g., asymmetric facade opening distributions and/or interior masonry walls).

- (b.1) *Modeling of the diaphragm.* The presence or lack of a diaphragm in the model should be in accordance with the function of the diaphragm in the structural system at hand. The in-plane rigidity of the diaphragm is an important consideration to account for in the model, particularly because of the fact that masonry buildings tend to be very stiff and the relative diaphragm-to-wall element in-plane stiffness will define the distribution of inertia loads from the floor to the vertical seismic load resisting elements.
- (b.2) *Modeling of the diaphragm connection with the walls.* Furthermore, as far as the modeling of the diaphragm is concerned, it is important to consider in the model whether its connections with the vertical masonry elements justify the use of a deformation fully compatible FE nodal connection, transferring load. The same is true for the roof structure, which is normally simply supported on the masonry walls, and sliding of the roof trusses on the walls is often possible under differential lateral seismic movements across walls.
- (c) *Modeling of the mass.* The conventional frame analysis assumption of a lumped mass

idealization is not justified in masonry modeling, and, instead, the model should incorporate distributed masses; due to the large masonry element size (compared to the normal operational loads of the building) and often the lack of a heavy concrete diaphragm, loads are not distributed according to the lateral stiffness of the elements. For this reason, three-dimensional modal dynamic analysis should at best be adopted, reflecting more accurately the system deformation and the load path of the inertia forces from the diaphragm to the foundation. Similarly, out-of-plane effects need also to be taken into account in a “distributed with height” sense for assessing the in- and out-of-plane interaction of forces to the walls, the dynamic connection forces at the wall intersection, and the seismic deformations and forces at the roof-to-wall connections.

- (d) *Modeling of the building foundation.* Masonry building response and past deformation history are affected by the deforming foundation at the base of the building. Consequently, full foundation fixity is often an unrealistic assumption, given that the stresses under the masonry wall may be relatively high. Evidence of cracking around openings or unsymmetrical distribution of cracks in an existing masonry building is often the effect of differential settlements due to variable ground conditions in plan, such as the presence of an abandoned well or a septic tank at one end, improper ground preparation at the time of construction, or a partial plan base-ment. For modeling the foundation, an acceptable practical modeling approach makes use of tensionless elastic springs, providing vertical, lateral, and bending restraint in the embedded footings.

FE Modeling of LBM Structures for Seismic Analysis

From the analysis of the complexity of the response, the failure modes, and the fact that different technologies and materials comprise

masonry construction, practical modeling of masonry buildings for seismic analysis relies on the use of FE models and follows two different techniques (Fig. 13):

- (i) The less refined “global” (phenomenological) macromodels, suitable for the analysis of entire LBM buildings. In this case, the walls, piers, and spandrel beams of the masonry structure are modeled using one-dimensional line elements with nonlinear characteristics. These macromodel elements (Fig. 13d) are characterized by equivalent axial load, bending, and shear interaction response characteristics. Such models have been used both for elastic and inelastic three-dimensional seismic analysis for design, assessment of seismic vulnerability, and fragility studies of masonry buildings under monotonic or cyclic loading.
- (ii) The refined “local” FE micromodels where the entire masonry building or a plane portion of the building, such as a masonry façade under planar response, is modeled using two- or three-dimensional FE approximations, with associated material and loading description (Fig. 13c). In terms of geometric representation, thick shell or across the length and through thickness brick FE approximations are adopted, possibly coupled with beam FE for the reinforcement, if any. Even more refined micromodel approximations have been adopted in research studies, in which the actual masonry unit and mortar have been separately modeled using brick and plate elements, respectively.

In terms of material approximation, phenomena such as cracking and compression nonlinearity or the presence of steel are smeared within the element integration area through equivalent stiffness and resistance modifications at the FE integration point. Models of this type have been used in the parametric investigation of conventional or historical masonry construction and for the validation of test results. Complexity and computational cost and resources are the

primary issue in this case as well as in certain aspects, the actual ability to model the material behavior under cyclic loading conditions.

Macromodels for Entire Building Analysis

Since the use of micromodels is too expensive and complicated for entire building analysis under seismic excitations and due to the fact that available software capabilities are often limited in handling such FE micromodels, equivalent FE macromodels are being used for practical seismic analysis of LB or NLB masonry construction.

For load-bearing masonry, the usual modeling conventions adopted in conventional frame building analysis are also adopted for masonry buildings as well: roof and diaphragm elements are modeled using line FE, or plain diaphragmatic action is enforced (if it exists). Similarly, wall piers, columns (pilasters), and spandrels are modeled at their centerline using equivalent or actual property line FE with linear or nonlinear characteristics, while the element joint regions are modeled using infinitely stiff elements and/or rigid zone transformation models depending on the analysis software conventions.

For inelastic analysis, phenomenological axial, shear, and flexural constitutive relations should be specified, possibly with cracking and post-failure modeling capabilities and, if possible, interaction of axial/flexural and shear stresses. Where this is not possible and given that the variation of axial loads is not high for low-rise buildings, uncoupled values may be assumed based on initial state vertical load levels.

Masonry building macromodels for inelastic analysis evolved from: (i) the simplified weak spandrel strong pier model, whereby spandrels crack early and are neglected (therefore the piers are considered to act as uncoupled cantilevers joint by hinged rigid link beams at the floor levels) (Fig. 14b); (ii) the strong spandrel weak pier model (the shear frame analogy), whereby the piers crack first and are therefore assumed to deform with their inelastic characteristics, the spandrels remaining relatively rigid (Fig. 14c); and (iii) the equivalent frame model, where the masonry structure is modeled as an assembly of

Seismic Analysis of Masonry Buildings: Numerical Modeling, Fig. 13 Modeling example of a historical masonry building in Lefkada, Greece, built of timber confined plinth masonry walls at the upper floor on

a stone masonry ground floor. (a) Photo. (b) Bearing structure. (c) Micromodel. (d) Macromodel (Vintzileou et al. 2007). Note that several load-bearing elements in the model are omitted for clarity

vertical pier and horizontal spandrel line elements interconnected by rigid joint regions (Fig. 14d): the geometry of the joints is obtained from the geometry of openings and an equivalent pier height, which is defined by the extent of cracking observed in the vertical elements following an earthquake or, if uncracked, assuming a crack inclination at about 30° that extends from the opening toward the joint (Lagomarsino et al. 2013).

For the constitutive modeling of inelastic FE macromodels under static seismic-type load, the multilinear (simplified or more refined) shear force–interstory drift or bending moment–pier rotation diagrams of Fig. 11 have been proposed

by several investigators for modeling both the in-plane shear and the flexural response of masonry wall piers, incorporating the different failure mechanisms of these elements (Fig. 15).

Magenes and Calvi (1997) proposed that the peak shear resistance R_u (Fig. 15) of a rocking masonry wall pier bearing an axial load P is given by:

$$R_u = \frac{D^2 t}{H_0} \frac{p}{2} \left(1 - \frac{p}{k f_u} \right) \quad (2)$$

where D and t are the length and thickness of the pier; H_0 is the effective height equal to the shear span, namely, the height to zero moment, taken as

Seismic Analysis of Masonry Buildings: Numerical Modeling,

(c) The weak pier and rigid spandrel shear frame model. (d) The equivalent frame model using spandrels, piers, and rigid joint regions (Lagomarsino et al. 2013)

Seismic Analysis of Masonry Buildings: Numerical Modeling,

Fig. 15 Model of the wall pier and lateral load deformation constitutive relation under axial force

being equal to the pier height, for cantilever piers, and half the pier height, for piers in contraflexure; p is the average vertical load pressure, equal to the axial load P divided by the wall area ($p = P/Dt$); f_u is the compressive strength of the masonry; and k is a coefficient that depends on the stress distribution at the toe of the wall ($k = 0.85$ for an equivalent rectangular stress block; see Fig. 15).

For shear failure mechanisms of brick masonry walls, when mortar bed and head stone failure is involved, they proposed to adopt a Mohr–Coulomb friction model for the wall, namely:

$$R_u = Dt\tau_u = Dt(c + \mu p) = Dt\left(c + \mu \frac{P}{Dt}\right) \quad (3)$$

where, in addition to the parameters defined above, τ_u is the average masonry shear strength; μ is the Coulomb friction coefficient; and c the cohesion of the wall (namely, the average frictional resistance at $P = 0$). Both of the latter parameters are global material constants for the wall and are obtained from testing of masonry elements. Following micromodel analysis at failure and comparison with test results, their model accounted for two types of shear wall failure, namely:

- (i) Failure at the cracked wall ends, with the peak shear strength τ_u being resisted in the compression area of the cracked section D' by t , where D' (the compressed portion of

the wall length D) is obtained by equilibrium of normal force and moment (Eq. 4a):

$$D' = \beta D = \left(1.5 - \frac{3V}{P} \frac{H_0}{D}\right) D \quad (4a)$$

- (ii) Failure at the mid-height of the wall, with the maximum shear strength τ_u being resisted by the entire wall thickness (area D by t) decreasing in an inverse linear manner with the wall shear span ratio H_0/D :

$$R_u = Dt \frac{\tau_u}{1 + \frac{H_0}{D}} = Dt \left(\frac{c + \mu p}{1 + \frac{H_0}{D}} \right) \quad (4b)$$

The shear strength of the wall in diagonal tensile failure is therefore given by the minimum strength of the two resisting mechanisms – failure modes:

$$R_u = Dt \tau_u, \quad \tau_u = \min \left\{ \left(\frac{1.5\bar{c} + \bar{\mu}}{1 + \frac{3\bar{c}H_0}{pD}} \right), \left(\frac{\bar{c} + \bar{\mu}p}{1 + \frac{H_0}{D}} \right) \right\} \quad (5)$$

It is further noted in the above expressions that the coefficients of friction and cohesion μ and c may be modified so as to obtain effective values $\bar{\mu}$ and $\bar{c}$, respectively, corrected for the geometry of the masonry unit, in accordance with the fact that the expressions above sometimes overestimated the experimental value of strength, due to the influence of the masonry headjoints.

- (iii) In addition to shear failure by Coulomb friction at the joints, shear failure due to in-plane cracking of the bricks was also experimentally observed for weak brick and strong mortar, in the presence of high axial stresses. It was proposed that the shear strength be estimated in this case in terms of the tensile strength of the bricks f_{bt} , following Eq. 6:

$$R_u = Dt \tau_b = Dt \frac{f_{bt}}{2.3 \left(1 + \frac{H_0}{D}\right)} \sqrt{1 + \frac{p}{f_{bt}}} \quad (6)$$

and the minimum of the values (Eqs. 5 and 6) used for resistance. In terms of deformation, the wall pier deformation corresponding to the ultimate strength (d_{Ru} , Fig. 15) was found to be close to 0.5 % of the wall height H in most test results they performed or evaluated (Magenes and Calvi 1997).

Detailed Micromodels for Seismic Analysis

In addition to the macromodels above, micromodels have been proposed and are employed for equivalent static linear or nonlinear seismic analysis of masonry buildings and (primarily) historical structures; furthermore, micromodels have also been used to calibrate macromodel topology and the masonry wall failure and constitutive response. Micromodels idealize masonry in detail using:

- (i) Two-dimensional thick plate and shell elements that account for both in-plane and out-of-plane stiffness and resistance characteristics (for out-of-plane bending effects of the walls). The use of shell element elastic models is quite common in the seismic analysis of masonry structures, since they do not require excessive computational resources and provide the basic load path and demand concentrations within the building, accounting for complex geometries and multitude of materials, such as timber, masonry, etc. (Fig. 13c). These are therefore suitable to use in entire building seismic analysis models.
- (ii) Three-dimensional (brick) FE models of the entire masonry structure, taking into account in the model both complex geometric idealizations of the structure and the foundation and the material complexities associated with the presence and interaction of several different materials with complex constitutive characteristics, such as: stress-strain

nonlinearity due to cracking or crushing; tri-axial capacity interaction and volumetric dilatancy under loading for the mortar, concrete, stone, or brick; yielding or pullout phenomena of the reinforcement where it exists; interface failure between brick, mortar, or steel (where it exists); and inelasticity of timber.

Depending also on the capabilities of the software adopted for the seismic evaluation, micromodels adopted for modeling of inelastic seismic response of LBM buildings include:

- The smeared representation models. These model nonlinearity as spatially averaged, by considering the distributed cracking of masonry in the vicinity of the FE integration points and/or the average constitutive response of masonry over the entire FE integration volume (area) using suitable two- or three-dimensional inelastic constitutive behavior and a strength interaction surface. Plane stress or three-dimensional yield surface characteristics have been proposed for CMU, brick masonry, or stone, possible candidates being, among others, the models proposed by Gambarotta and Lagomarsino (1997) and Stavridis and Shing (2010).
- The discrete representation models. These model nonlinearity discretely through detailed FE modeling of all different material regions involved, namely, individual modeling of the mortar as a brick, shell, or zero-length contact FE, the masonry units and the concrete (where present) as a brick or plain stress shell element (primarily for industrially manufactured units of constant geometry), and the steel or timber reinforcement (where present) as truss or beam elements (for CM or RM buildings).
- As a special case of these are the discrete crack representation models, which further monitor crack formation using fracture energy criteria and the evolution of cracking within the masonry element through mesh redefinition (average material representation) and/or through or along predefined mortar beds (where these exist in physical and model

space), using suitable contact friction elements.

- Models based on the discrete element idealization that fall into this category have been promoted for modeling primarily historical monuments; in this case, the brick units (or stone building blocks) are modeled as individual deformable or undeformable volume elements, and their interface is described with Coulomb frictional contact-separation characteristics.

Modeling of NLBM Infilled Frame Buildings for Seismic Analysis

Due to the abundant use of CM infilled panels in steel and RC frame structures, the seismic analysis modeling of entire frame buildings with NLBM infills is also briefly examined herein for completeness. Only the modeling of the infills is considered herein, since the modeling of the entire frame is beyond the scope of this text. It should be noted, however, that in the design of RC frame buildings, the infills are (and have been) neglected in the structural model assuming that these contribute only to the inertia mass. Only recently modern seismic codes (EC8 2004) provide structural forming and detailing guidelines for taking into account possible adverse response effects due to the presence of the infill; furthermore, PBD methodologies for the assessment and retrofit of existing RC frames require that these be fully accounted for in the seismic model, in their as-built configurations and properties (FEMA-356 2000).

Infill panels provide a large increase in the lateral stiffness of the confining frame with a disproportionate increase in its mass; consequently, masonry infilled frames exhibit short fundamental periods compared to the bare frame structure and therefore attract higher inertia forces at shorter drifts. Properly engineered infill panels, constructed of good quality modules and mortar and adequately wedged into the panel, without excessive openings and a regular in plan and in height configuration, will provide the bare frame structure with considerable overstrength and stiffness enhancement.

Seismic Analysis of Masonry Buildings: Numerical Modeling,

Fig. 16 Damages to infilled RC frames following the 1985 Mexico City earthquake. (a) Damage of the confining frame elements. (b) Out-of-plane failure of the infills. Note that the panels were confined by RC lintels and pilasters tied to the RC frame

Masonry infills, like other masonry elements already discussed, tend to fail in plane or out of plane (Fig. 16) following similar mechanisms as other masonry elements (diagonal thrust or tension, corner compression, sliding at joints through brick or mortar, out-of-plane collapse, etc.). Such a full or partial failure of the infills will lead to local failures of the confining elements due to the formation of unintentional short column effects or due to a shear failure of the top of the column or the beam–column joint. For these reasons, in the PBD assessment approach of existing structures, the infills need to be accounted for in seismic analysis.

In modeling infilled frame buildings in practical seismic analysis of entire structures, macromodels are used for the panels, as shown in Fig. 17. Micromodels have also been adopted in the literature, however primarily for research applications and in order to calibrate the macromodel parameters. The use of macromodels stems from the observation that, due to the partial contact separation of the panel from the surrounding frame elements under lateral response of the infilled frame, the function of the infill can be modeled as an equivalent axial load-bearing diagonal strut element resisting

compression only in the direction of the lateral force. The strut has a thickness t_{inf} equal to the panel thickness and an equivalent width W_{eff} based on the frame to panel contact length; proposed strut widths adopt contact lengths that account for the relative stiffness characteristics of the confining frame and the infill panel in terms of $\lambda_{h,L}$ (Stafford Smith and Carter 1969), where $\lambda_{h,L}$ expresses the relative stiffness of the infill and the concrete elements assuming elastic contact (Fig. 17a):

where E_m and E_c are the Young's moduli of masonry and concrete; I_{col} is the uncracked moment of inertia of the confining column elements; θ is the geometric inclination of the infill strut (Fig. 17a); L_{inf} and H_{inf} are the clear length and height of the infill; and H_c is the centerline distance between the beams. For seismic applications cross strut configurations are used with compression only properties (Fig. 17b). In order to model the effect of short column formation in the infilled frame response, multiple strut configurations as shown in Fig. 17b have also been proposed (Crisafulli et al. 2000). Their use is recommended in the case of asymmetric infill configurations within a floor, such as infilled frame bays next to open bays or end bays of the infilled frame.

Summary

The seismic response and forms of failure for different types of masonry construction have been presented and discussed. It is commonly believed that masonry buildings, being the most common form of past construction in all seismic affected areas, as well as a financially viable alternative for new low- to mid-rise construction, they need to be evaluated for seismic loading, due to the seismic vulnerability of such structures as it has been proven in numerous seismic events, past and recent.

Several modeling conventions have been proposed so far and are still under rigorous research investigations, for the seismic analysis of masonry buildings. Overall, these range, depending on the capabilities of the FE code at hand and also on the reliability of the structural information available, from simple strut-and-tie models (the equivalent frame analysis models, which are also referred to as macromodels) to the refined micromodels, using plane or three-dimensional FE analysis tools, both linear and nonlinear material-wise and geometry-wise.

Not all methods are suitable for all cases, and often analysis “overkill” for a problem that is quite complex to model will give a false sense of security: due to the complexity of the problem, involving different masonry materials (brick, mortar, stone, rubble, and also RC or steel and timber), different types of construction (LB or NLB, CM), and different structural topologies (low or mid rise, with or without diaphragms, irregular in plan or elevation, with openings, with flexible foundation), equally complex methods should be used, justifying the accuracy of the input information, namely, the material properties for all materials involved in the construction and an adequate knowledge of their interaction.

For entire structural models, macromodels or area micromodels with averaged properties over the FE region are adequate to capture global quantities (forces and deformations) and seismic performance. For detailed damage prediction (cracking, crushing, region disintegration under overload), three-dimensional FE models are adopted, using either deformable elements with smeared or discrete cracking representation or discrete FE models with contact friction interfaces, where crack spreading is not feasible (e.g., URM construction and historic building analyses). These models, although they provide realistic damage predictions compared to observation and test, are too detailed and complex to be applied to ordinary construction, and they need to be substantiated by adequate testing in order to establish the material behavior as input to the FE model.

Introduction

Reinforced concrete slabs rigidly connected with steel girders have been used to form the basic superstructure of large numbers of deck bridges for many decades. This is due to the fact that the composite construction method offers the bridge engineers a great variety of solutions for different types of problems. A typical composite cross section of a highway bridge is shown in Fig. 1. A series of parallel steel girders are rigidly connected with a reinforced concrete slab through shear connectors. The shear connectors installed are mostly welded studs allowing use of the deck as part of the top flange (*deck plate girders*). The longitudinal bending of the composite T-girders, at sagging bending areas, results in tension in steel and compression in concrete. The simultaneous operation of both of these materials generates the composite action which is the most important feature for the formation of stiff and high-strength cross sections. At hogging moment areas, concrete is considered to be fully cracked, and only the slab reinforcement, but not concrete, contributes to bending resistance.

In pure steel bridges the reinforced concrete slab is replaced by an orthotropic steel deck. This is composed of the steel deck plate; the longitudinal, mostly trapezoidal, stiffeners; and the crossbeams (Fig. 2). Orthotropic are lighter than concrete decks. However, they require high fabrication costs due to intensive welding operations and are susceptible to fatigue. Therefore, pure steel bridges (see EN 1993-2 2006) are nowadays mostly limited to cases where it is essential to limit the deck weight, e.g., for very large spans, movable bridges, etc. The present article refers mainly to composite bridges that constitute the vast majority in modern steel bridge construction.

Modeling for analysis is required in order to determine internal forces and moments, deformations, and vibrations of bridge decks including bearings, piers, abutments, piles, etc. In addition models should include the foundation when soil-structure interaction is accounted for. A bridge analysis model should be based on the following criteria:

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 1 Layout of a typical composite deck bridge

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 2 Steel bridge with orthotropic deck

- It should reflect the structural response in terms of deformation, strength, and local and global stability.
- It should include as many as possible structural elements and parts of the bridge deck (cross frames, stiffeners, etc.) and their possibly eccentric connections.
- It should also include bearings and piers individually, piles, etc.
- It should cover all construction stages and loading cases.

- Loads should be easily introduced.
- It should allow the performance of dynamic analysis and include the most important modes of vibration.
- The resulting output should be such that it enables easily the execution of the code-prescribed verifications.
- It should be supported by commercial analysis and design software.

Models for Seismic Analysis

There exist several possible models for bridge seismic analysis that could be employed depending on the bridge configuration, the bearing types, the connection between superstructure (bridge deck) and piers or abutments, the type of foundation with possible soil-structure interaction, etc.

Figure 3 shows possible modeling levels for seismic analysis of steel and composite bridges, starting from the simple to the comprehensive ones. Simple models, like the first three in Fig. 3, can be used for preliminary seismic analysis. They may be employed for the derivation of seismic forces and displacements on bearings, piers, foundations, or the soil. Comprehensive models, like the last three of Fig. 3, are mostly used at the main design phase since they also cover analysis for construction stages and service conditions where other loads due to traffic, wind, temperature, time-dependent concrete effects, etc. must be taken into account.

In the following the various analysis models for steel and composite steel-concrete bridges are presented. Models for superstructures (decks) are linear since decks are expected to remain elastic in the seismic situation. Any inelastic activity should be restricted to bearings, piers, piles, soil, etc. For bearings and piers, nonlinear characteristics are provided. For other elements (piles, abutments, soil), reference is made to other chapters.

Rigid Deck Model

In this model the superstructure is represented as a single mass, M_{dir} , acting on a spring of stiffness

K_{dir} . M_{dir} includes the entire mass of the deck without the mass of the piers. The global spring stiffness K_{dir} represents the combined stiffness of bearings and piers and the foundation of soil and is calculated from

$$\frac{1}{K_{dir}} = \frac{1}{\sum K_{bearings}} + \frac{1}{\sum K_{piers}} + \frac{1}{\sum K_{foundation}} \quad \text{where } dir = \text{direction X or Y} \quad (1)$$

The fundamental period for this single mass oscillator is calculated from (see Fig. 3a)

$$T_{dir} = 2 \cdot \pi \cdot \sqrt{\frac{M_{dir}}{K_{dir}}}, \quad M_{dir} = \sum m \quad (2)$$

The seismic forces acting on the entire deck $F_{EA, dir, tot}$ are determined from the relevant response spectrum. The seismic forces of bearings at the top of one pier i may be determined from

$$F_{bearing, i} = \frac{\sum (K_{bearing, i} + K_{pier, i} + K_{foundation, i})}{K_{dir}} \cdot F_{AE, dir, tot} \quad (3)$$

This model may be applied for the longitudinal direction of straight bridges with continuous decks, when the mass of the piers is less than 20 % of the tributary mass of the deck. The model may be also applied for the transverse direction provided that all conditions (a) to (c) referred below apply (see EN 1998-2 2005):

- (a) $L/b \leq 4.0$

where

L is the total bridge length and

b is the width of the deck.

- (b) $\Delta d/d_a \leq 0.2$

where Δd and d_a are, respectively, the maximum difference and the average value of the displacements in the transverse direction of all pier tops under $F_{AE, Y}$.

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 3 (continued)

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 3 Analysis models for seismic design of steel and composite bridges. (a) Rigid deck

models. (b) Individual pier models. (c) Spine models. (d) Grillage models. (e) 3D beam models. (f) Comprehensive models

- (c) The theoretical eccentricity between the mass center of the deck and the stiffness center of the supporting members does not exceed 5 % of the deck's length.

The application of the rigid deck model may be extended to cases where bearings with damping properties are employed. The bearing stiffness K_{bearing} is expressing the secant

stiffness of the bearing device and is determined iteratively to correspond with the bearing's displacements. In addition higher damping values are achieved, so that a reduction factor must be employed to the resulting seismic forces. More detailed information is given in sections “[High-Damping Reinforced Elastomeric Bearings](#)” and “[Lead Rubber Bearings \(LRB\)](#).”

Individual Pier Model

This model may be used for seismic analysis of bridges in the transverse direction. Each pier and the associated part of the superstructure is considered separately and represented as a single mass oscillator. The mass of the oscillator is $M_{\text{pier}, i}$, and includes the mass of the deck between half distances of piers, while $K_{\text{pier}, i}$ represents the pier stiffness.

The fundamental period for pier i is calculated from

$$T_{\text{pier}, i} = 2 \cdot \pi \cdot \sqrt{\frac{M_{\text{pier}, i}}{K_{\text{pier}, i}}} \quad (4)$$

Based on the fundamental period, the seismic forces acting on top of the pier $F_{\text{AE}, Y}$ are determined from the relevant response spectrum. The individual pier model is not appropriate for curved or skew bridges, bridges with varying spans, varying pier lengths, etc. It may be used for long bridges where each pier is able to act independent of the rest of the bridge. These requirements are met when following conditions apply:

- The seismic action in transverse direction is mainly resisted by piers.
- There is no significant interaction between adjacent piers.
- $0.90 \leq \frac{T_{\text{pier}, i}}{T_{\text{pier}, i+1}} \leq 1.10$.

Spine Models

Spine models are appropriate for performing multimodal dynamic analysis on bridges and let the seismic forces resisted by each pier determined in a “natural” way in accordance with their relative stiffness. They may be employed for “normal” bridges, normal meaning more or less straight, low skew, narrow deck, and cross section with limited distortion, i.e., with rigid closely spaced transverse frames or crossbeams.

In spine models the bridge deck is represented by beam elements that are positioned at the centroid of the cross section and have six (6) degrees of freedom (DOFs) at end nodes (Fig. 4). The degrees of freedom are the translations (u, v, w) along the principal axes coordinate system (x, y, z) and the corresponding rotations ($\theta_x, \theta_y, \theta_z$). The resulting internal forces (N, M_y, M_z) act at the gravity center, while the shear forces and torsion moments (V_y, V_z, M_x) at the shear center. Cross-sectional warping may be taken into account by introduction of an additional seventh DOF per node as independent variable ($\theta'_x = d\theta_x/dx$), which results in the bimoment M_w as additional internal moment (see Kindmann and Kraus 2011).

The initial beam cross section is the gross cross section. However, for wide flanges, either of concrete or steel, effective widths must be introduced to consider shear lag effects (Fig. 5). Although effective widths vary along the length of the bridge, they are smaller at internal supports

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 4 Representation of the bridge deck by 7 DOF beam elements

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling,

Fig. 5 Gross and effective cross section for wide concrete or steel flanges

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 6 Determination of the cracked regions for composite bridges

than at spans, fixed values, equal to those at spans, are considered for global analysis. It should be mentioned that effective widths are calculated differently for concrete flanges than for steel flanges (see EN 1993-2 2006 and EN 1994-2 2005).

For composite bridges the flexural stiffness, denoted as $E \cdot I_1$, is calculated for the uncracked section in regions where concrete is in compression. For seismic analysis, the short-term modulus of elasticity of concrete is considered. At hogging moment areas, concrete is in tension for beam-type bridges. Cracking of concrete in those regions is considered by introducing the flexural stiffness $E \cdot I_2$ of the “cracked” section in which the contribution of the concrete slab is neglected. For continuous bridges the cracked region may be considered to be adjacent to the internal supports in a length equal to 15 % of the corresponding span length (Fig. 6). The 15 % rule constitutes a rough

approximation of the true behavior (EN 1994-2 2005), however, for the purpose of seismic analysis is considered as adequately precise.

As an alternative to the fully cracked section, the *tension stiffening effect* of concrete may be taken into account in the cross-sectional properties by increasing the area of steel reinforcement by the factor $1/[1 - (0.5 \cdot f_{ctm})/(\rho_{s, \text{tot}} \cdot f_{sk})]$ where $\rho_{s, \text{tot}}$ is the total reinforcement ratio, f_{ctm} the mean tensile strength of concrete, and f_{sk} the characteristic yield strength of the reinforcing steel (see Vayas and Iliopoulos 2013).

The torsional stiffness $G \cdot I_t$ for composite box girders may be calculated from mechanics, where the shear modulus of concrete is taken into account by introducing 0.2 or 0 as the Poisson’s ratio for uncracked and cracked regions correspondingly.

Although the superstructure is represented by a single beam in spine models, bearings and piers

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling,
Fig. 7 Two-span continuous bridge. (a) Physical model and (b) numerical spine model

appear individually in the model. Figure 7a shows for a two-span continuous composite girder bridge that is supported by two pile bent abutments and one two-column bent. The cross section is a composite section consisting of two I-girders and a concrete deck. The girders rest individually on bearings. Figure 7b shows the spine model for this bridge. The cross section of the superstructure is represented by a single beam element, while each bearing by two horizontal springs. The beam and the springs are coupled by a rigid link that represents the crossbeam. Below the crossbeam are the two piers that are represented by beam elements that rest on translational and rotation springs representing the pile foundation and the soil. Similar conditions apply to the abutments, where each bearing is represented by two horizontal springs, coupled in series with horizontal abutment/foundation springs.

Grillage Models

General

The most popular computer-aided modeling method for the analysis of composite bridges is the simulation by means of a plane grillage system. This is due to the fact that this system is easy to apply and comprehend as well as that it has been proved to be sufficiently accurate for a wide

variety of bridge decks. In this model, the structure is idealized by means of a series of longitudinal and transverse beam elements rigidly interconnected at nodes. Each element is given an equivalent bending and torsion inertia to represent the relevant portion of the deck.

Plate Girder Bridges

Figure 8 illustrates a grillage representation of a simply supported composite bridge with four main girders that may similarly be applied to continuous systems or different number of main girders. Longitudinal grillage members are arranged to represent the main girders with the inertia properties of the composite section (steel section with a part of the slab corresponding to the effective width). Transverse members represent the deck slab with thickness h_c equal to the thickness of the slab and width b equal to the distance between transverse beams; it is convenient to select b equal to the distance of the axle loads. A non-cracked flexural rigidity for the slab elements is usually applied. The torsional rigidity of the transverse slab elements can be set to zero. The total in-plane second moment of area of the slab is equally shared to the two extreme main girders (A and D), while the intermediate girders (B and C) are given $I_z = 0$. This is because wind loads mainly act on the edge girders of the bridge. In case of intermediate cross girders whose stiffness may influence the transverse distribution of

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 8 Grillage model of a plate girder bridge

the vertical loads, these girders are taken into account by appropriate modification of the transverse member properties. In case of long distances between adjacent transverse beams, X-bracing concrete elements may need to be set in the deck's plane in order to simulate the diaphragmatic behavior of the deck slab.

Reinforced elastomeric bearings, usually implemented in bridges, are represented by three axial springs of equivalent stiffness corresponding to the relevant stiffness properties in horizontal and vertical directions; the calculation of the bearings' stiffness is presented in section "[Reinforced Elastomeric Bearings](#)." The axes of the main beams coincide with the center of gravity of their cross sections. However, the bearings are positioned beneath the lower flange. Accordingly, rotations of the main girders result in horizontal deformations u of the bearings and additional support reactions R_{bear} . The support nodes are therefore put at a lower level from the grillage members and are connected to the longitudinal beams by rigid vertical bars whose height h is equal to the distance between the center of gravity of the main composite beams and the bottom flange; for better accuracy, the shear center of the cross section should be used which is assumed to be the "real" center of rotation. In case of intermediate cross girders whose stiffness may influence the transverse distribution of the vertical loads, these girders are taken into account with beam elements of an appropriate stiffness.

At piers truss elements are used for the representation of the cross braces. Due to the height h of the rigid elements, the geometry of the bracings in model may not follow the exact geometry of the bracings in real structure. A height adjustment for the rigid elements may then be necessary. This should be done only for the purpose of estimating the forces of the bracing members due to horizontal loadings, i.e., wind or earthquake. It has to be stated that in most bridges the gravity center of the composite cross sections is located near the top flange. For such cases a height adjustment has little influence on final results.

Skew Bridges

In skew bridges the support abutments or piers are placed at angles other than 90° from the longitudinal centerlines of the girders (Fig. 9). The skew angle is usually defined as the angle between the longitudinal axis of the bridge and a line square to the supports. The presence of skew affects the geometry and the behavior of the structure. Special phenomena, like twisting and out-of-plane rotation of the main girders during concreting, uplifting forces at bearings, and fatigue problems due to out-of-plane web distortion, make the analysis and design of skewed bridges intricate. The transverse elements representing the slab are usually oriented perpendicular to the main girders (orthogonal mesh); this is the most usual grillage model used by the designers. Alternatively, the transverse members

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 9 Grillage models for skew and curved plate girder bridges

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 10 Grillage model of a simply supported box girder bridge

can be placed parallel to the line of supports (skewed mesh). Generally the skewed mesh is convenient for low skew angles ($\theta < 20^\circ$) or when the intermediate bracing is not arranged square to the main girders.

Curved Bridges

Curved decks pose no particular problem for grillage modeling (Fig. 9). A curved bridge deck can be represented by a grillage of curved members or of straight members. Some computer programs support curved members but others do not. Generally, a grillage of straight beams with a very fine mesh is for small values of curvature sufficiently accurate. For highly curved bridges, 3D – or FE – models should be used (Adamakos et al. 2011).

Box Girder Bridges

A grillage model can be implemented also for single-box girder bridges (Fig. 10). The box girder is divided in two opened composite cross sections in which the shear lag effect in the deck slab and the lower flange is considered through the effective widths. The grillage is thus composed of two main composite girders A and B transversely connected with beams representing the internal braces or diaphragms, not the slab. The torsional rigidity of the composite box girder is represented in the model by a fictitious girder located between the main composite girders. The central girder comprises also the whole bending ($I_{Z, tot}$) – and shear stiffness of the deck slab ($A_Y \approx$ slab area). The flanges for girders A and B extend over their effective

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 11 (a) Shear flow of the box section due to *St. Venant* torsion. (b) Deformation of cross frames

widths. Care should be given that these widths are different for concrete and for steel flanges and also different for analysis and for design.

Longitudinal stiffeners in the bottom flange are considered by “smearing” them over the flange width. The bottom flange is then considered having a total thickness of $t_{tot} = t + t_{add}$, where t is the thickness of the panel and $t_{add} = \sum A_{stiffeners} / b_f$. The same procedure is followed for bridges with orthotropic steel deck, where the top flange panel is taken into account with increased thickness due to “smearing” of the longitudinal stiffeners. However, the increase in thickness does not apply to the web panel due to the fact that existing longitudinal stiffeners are usually placed only to enhance its buckling resistance and are not necessarily continuous.

Transverse beams in the global model represent the flexibility of the cross frames or of cross braces. Since a single beam shall represent an entire frame, the definition of its properties requires some preliminary analysis. The beams are considered as rigid in bending but flexible in shear deformations. Accordingly they are assigned an infinite in-plane second moment of area and a shear area A_s . Cross frames or cross braces, and accordingly the transverse beam, resist part of the torsion while they are not strained due to global bending. A global torsion moment M_t is partly resisted by the *St. Venant* action and partly by the cross frames or cross

braces. This torsion is split into antisymmetric loading $\pm P = M_t / L$ (see Fig. 11). The *St. Venant* shear flow is given by

$$T = \frac{M_t}{2 \cdot A_0} = \frac{P \cdot L}{2 \cdot A_0} \quad (5)$$

where A_0 is the shaded area in Fig. 11a.

Therefore, the forces resisted by the cross elements are equal to

$$P_1 = P - T \cdot H_{inclined} \cdot \sin \varphi = P - T \cdot H \quad (6)$$

where $P = M_t / L$. It may be seen that the cross elements are resisting part of the global torsion. If the webs are not inclined ($\varphi = 90^\circ$), the force resisted by the cross elements is equal to:

$$\begin{aligned} P_1 &= P - \frac{P \cdot L}{2 \cdot H \cdot L} \cdot H \\ &= \frac{P}{2}, \quad \text{i.e., 50 \% of the acting forces} \end{aligned} \quad (7)$$

Subsequently the vertical deformation v of the cross frame due to antisymmetric loading $\pm P_1$ as determined before is numerically calculated (Fig. 12). Due to symmetry, only half of the cross section is analyzed and hinges are placed in the middle of the flanges. The two flanges and the web are represented by beam elements with cross

sections composed of the transverse stiffeners or transverse girders and an associated flange width. The effective width for the web and the bottom flange panels is equal to $30 \cdot \varepsilon \cdot t$, $\varepsilon = \sqrt{235 \cdot f_y}$, where f_y = yield stress in MPa and t = thickness of the web or bottom flange.

Orthotropic steel decks are represented in a similar way. For composite bridges with concrete decks, the cross section of the relevant beam element is composed of the transverse girder and the effective width of the concrete slab.

The deformation of a transverse beam is equal to $v = P \cdot L / (A_s \cdot G)$ where G is the shear modulus (see Fig. 12). By setting this deformation equal to the deformation of the cross frame calculated previously, the shear area of this beam is defined as equal to

$$A_s = \frac{P \cdot L}{v \cdot G} \quad (8)$$

where v is the deformation of the system of Fig. 11 due to the load P_1 given before.

Half-Through Bridges

Half-through bridges may be also represented by plane grillage models (Fig. 13). Main and cross

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 12 Deformation of the transverse beam of the global model

girders are represented by beam elements, the former with steel sections, the latter with composite section including the effective slab width. Lateral torsional buckling phenomena of the top compression flange cannot be captured by this grillage model. 3D models are then recommended.

3D Models

General

The structural representation of bridge decks with truss girders or I-shaped plate girders may be done by means of 3D models as proposed from Vayas et al. (2010, 2011) and Vayas and Iliopoulos (2013). Truss girders are represented by their chord and bracing members, while plate girders are transformed to equivalent trusses. Such models have been proven to be advantageous for modeling orthogonal, skewed, and curved bridges. Unlike grillage models, they are able to consider:

- Eccentricities among the structural elements of a bridge and therefore additional internal forces and possible load distributions
- The transversal variation in the level of the neutral axis
- Torsion and distortional warping effects
- The dispersed structural behavior of the deck slab, in which bending takes place in two directions
- Buckling phenomena of the steel girders during erection stages
- Diaphragms, bracing systems, and stiffeners – possible overload or fatigue effects are taken into account

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 13 Grillage model of a half-through bridge

Girder Representation

Steel and composite I cross sections are modeled by a “hybrid” truss as shown in Fig. 14. For the steel girder, the flanges of the truss are beam elements with a cross section composed of the flange and a part of the web of the steel girder. Comparative analyses showed that one third of the web height may be associated to the flange. Therefore, the flanges of the truss are T-sections consisting of the flange of the steel girder and one third of the web and are positioned at the center of gravity of the T-section. The webs are represented by diagonal truss elements with width equal to one third of the web height and thickness equal to the web thickness. It has been also shown that the cross-sectional area $A_d = h_w \cdot t_w / 3$ for the diagonals adequately corresponds to the shear stiffness of the web. The post-beams are located at a spacing $s \approx 5\%$ of the span of the bridge. This distance is generally acceptable for small and medium span bridges because the angle between the diagonals and the flange elements usually remains between 35° and 45° . Post-beams represent both the in-plane and out-of-plane stiffness of the web.

For a composite section the same procedure is followed, with the concrete slab represented by another beam element connected with the upper flange of the truss through the appropriate offset: offset = distance between the centroids C_c

and C_{fo} . The nodes of the elements that represent the slab are the same nodes of those representing the upper flange of the truss. It is recommended that a fine mesh is used for the beam elements of the concrete slab and the top flange of the steel girder so that a full shear connection is achieved. Without a fine mesh the beam elements of the slab may deflect differently than those of the top flange.

Slab Representation

Slabs are structurally continuous in both directions X and Y, and they resist applied loads by shear forces, bending moments and torques which are coupled with each other. For this reason it was previously mentioned that the transverse slab elements of the grillage models should not be used for the final design of the slab.

A grillage model which considers the dispersed bending and torsion stiffness of a solid slab is illustrated in Fig. 15. The grillage mesh should be sufficiently fine so that the grillage deflects in a smooth surface in a similar way as a real slab. A smooth deflected surface is equivalent to the requirement that the twist $\partial^2 w / \partial x \partial y$ is the same in orthogonal directions and that $m_{yx} = m_{xy}$. The spacing of the beams shouldn't be less than 2.5 times the slab depth. Transverse beams should have spacing similar to that of the longitudinal beams. It is also recommended that

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 14 Truss idealization for a steel-concrete composite girder

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 15 Grillage model for an isotropic solid slab

the row of longitudinal beams at each edge of the grillage should be located in a distance of $0.3 \cdot h_c$ from the edge of the slab, where h_c is the slab depth (see Hambly 1990). This is where the resultant of the shear flows is located. The width of the edge member for the calculation of I_T should be therefore reduced to $b - 0.3 \cdot h_c$.

The 3D Model Implementation

The grillage model for the slab's representation in Fig. 15 can be combined with the truss model which is shown in Fig. 14. Figure 16 illustrates a 3D model which is recommended for the structural analysis both of simple and continuous composite bridges. Attention must be paid so that the grillage has its longitudinal members coincident with the center lines of the steel sections. At sagging moment areas, longitudinal slab elements are used with their uncracked properties. At hogging moment areas, concrete is considered as fully cracked and the total reinforcement is positioned due to simplicity at center of the slab. Transverse slab elements can be considered with their uncracked properties.

One can see that the model can be set up in a detailed way by taking into account all the

necessary structural elements, i.e., cross-bracings, bearings, etc. Imperfections, precambering, and girders with variable cross sections can also be implemented in the model. Therefore, structural phenomena which may be difficult or impossible to investigate with plane grillages are included in the outputs of the 3D model, e.g., arch effects in integral bridges with longitudinally variable cross sections.

Modeling of Bearings

General

Bridge decks rest usually on bearings that are important elements for seismic analysis and design. Most of the bearings, especially modern bearings, provide seismic isolation to the bridge, reducing the forces on piers, foundations, and the soil. Seismic isolation is provided due to the low stiffness of such bearings that results in a shift to longer fundamental periods and lower spectral values (see Chopra 1995). An appropriate representation of bearings in the structural model is essential for seismic bridge design and will be presented in the following. Bearings may deform

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 16 3D model of a two-span continuous bridge

during seismic action in the nonlinear range. Accordingly linear and nonlinear characteristics are provided.

T_e is the nominal thickness of the elastomer layers.

dir = global direction X or Y.

Reinforced Elastomeric Bearings

Reinforced elastomeric bearings (Fig. 17) consist of uniformly spaced layers of elastomer (natural or synthetic rubber) and reinforcing steel plates that obtain their bonding through the process of vulcanization. The equivalent viscous damping ratio for common elastomers ξ is less than 6 %.

Reinforced elastomeric bearings are introduced as linear springs in global analysis. The spring stiffness in each unrestrained horizontal direction may be obtained from

$$K_{dir} = \frac{A \cdot G_b}{T_e} \quad (9)$$

where:

$A = a \cdot b$ or $\pi \cdot D^2/4$ is the plan area of the bearings.

The shear modulus G_b considered has an increased value compared to $G = 0.9$ MPa of elastomers to account for the speed of loading in the seismic situation so that (see EN 1998-2 2005):

$$G_b = 1.1 \cdot G \quad (10)$$

Beyond this, upper and lower values of the shear modulus are introduced in the seismic combination with recommended values as follows:

$$G_{b,max} = 1.5 \cdot G_b = 1.65 \cdot G \quad (11a)$$

$$G_{b,min} = 1.0 \cdot G_b = 1.1 \cdot G \quad (11b)$$

Upper values are supposed to result in maximum forces, minimum values maximum displacements. However, this might not be always the case, depending on the resulting periods and

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 17 (a) Composition of reinforced elastomeric bearings. (b) Single DOF seismic analysis of a simply supported composite bridge with a rigid deck model

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 18 Layout and representation of spherical bearings

the spectral values. In vertical direction the bearing is practically incompressible so that the vertical displacement is considered to be restrained without use of springs.

High-Damping Reinforced Elastomeric Bearings

These are bearings in which the common elastomer is substituted by high-damping elastomer. Their equivalent viscous damping ratio ξ reaches values between 10 % and 20 %, while common elastomeric bearings have damping ratios ξ below 6 %. These bearings are modeled in global analysis as linear springs like common elastomeric bearings. The reduction in seismic forces

is taken into account by application of the reduction factor $\eta = \sqrt{10/(5 + \xi)} \geq 0.55$ on the forces determined from a response spectrum with 5 % damping.

Spherical Bearings

Spherical bearings consist of a sole plate that transfers loads from the superstructure, a concave spherical segment and a convex spherical segment that provides a mating surface for the concave segment and transfers load to the substructure (Fig. 18). PTFE (Teflon) sliding layers are provided between the three parts to allow horizontal displacements and rotation in all directions. Spherical bearings provide

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 19 Layout and representation of pot bearings

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 20 (a) Layout of lead rubber bearings. (b) Force-displacement behavior of lead rubber bearings

therefore only vertical support. They are accordingly represented by hinges allowing also horizontal displacements. Spherical bearings may be also guided to restrain displacements in one or both horizontal directions. In this case displacements in the relevant horizontal direction are restrained.

Pot Bearings

Pot bearings are based on the incompressibility of natural rubber when placed in a closed steel pot where natural rubber behaves like a fluid (Fig. 19). Pot bearings are able to transfer high compression forces in a small surface and allow rotations around all axes. They provide horizontal and vertical support while rotations are free. Provision of a sliding material allows horizontal displacements in which case the bearings provide only vertical support.

Lead Rubber Bearings (LRB)

These are common reinforced elastomeric bearings with low-damping elastomer and a cylindrical lead core that may reach damping values up to 40 % (Fig. 20a).

During cyclic loading the lead core is yielding and strain hardening so that the hysteretic response of the bearings, as illustrated in Fig. 20b, is typical for a yielding and strain hardening material. In analysis the bearings may be accordingly represented by a bilinear horizontal springs with elastic stiffness K_e for displacements up to the yield displacement and post-elastic tangent stiffness K_p for larger displacements.

The elastic stiffness may be determined from

$$K_e = K_R + K_L \quad (12)$$

where:

K_R is the shear stiffness of the elastomers.

K_L is the shear stiffness of the lead core.

The yield force is determined from

$$F_y = F_{Ly} \cdot \left(1 + \frac{K_R}{K_L}\right) \quad (13)$$

where F_{Ly} is the yield force of the lead core.

The force at zero displacement is equal to

$$F_0 = F_y - K_p \cdot d_y \quad (14)$$

The post-elastic stiffness is attributed to the lead core only and is calculated from

$$K_p = \frac{F_{\max} - F_y}{d_{bd} - d_y} = K_R \quad (15)$$

However, the above bilinear representation is appropriate for nonlinear analyses. For linear analysis the spring properties are linearized by introduction of the secant stiffness. This effective stiffness is written as

$$K_{\text{eff}} = \frac{F_{\max}}{d_{bd}} \quad (16)$$

The analysis must be iterated in this case by introduction of an initial value for K_{eff} and update it consecutively as a function of the resulting maximum displacement of the previous step.

Figure 20b indicates that lead rubber bearings dissipate energy when displaced beyond the yield displacement. The energy dissipation per cycle equals to the shaded area of Fig. 20b and may be determined from

$$E_D = 4 \cdot (F_y \cdot d_{bd} - F_{\max} \cdot d_y) \quad (17)$$

The energy dissipation may be transformed to increased damping with an effective damping ratio ξ_{eff} determined from

$$\xi_{\text{eff}} = \frac{E_D}{F_{\max} \cdot d_{bd}} = \frac{E_D}{2 \cdot \pi \cdot K_{\text{eff}} \cdot d_{bd}^2} \quad (18)$$

where all symbols are indicated in Fig. 20b. For linear analysis the value of ξ_{eff} is updated in each iteration step in order to determine the reduction factor for increased damping on the resulting seismic forces. When the rigid deck model is employed, all bearings are represented by a single spring with an equivalent stiffness and damping ratio determined from

$$K_{\text{eff}, \text{tot}} = \sum K_{\text{eff}, i} \quad (19)$$

$$E_{D, \text{tot}} = \sum E_{D, i} \quad (20)$$

where the summation refers to all bearings i .

The equivalent damping ratio for all bearings is calculated from

$$\begin{aligned} \xi_{\text{eff}, \text{tot}} &= \frac{E_{D, \text{tot}}}{2 \cdot \pi \cdot K_{\text{eff}} \cdot d_{bd}^2} \\ &= \frac{1}{2 \cdot \pi \cdot d_{bd}^2} \cdot \frac{E_{D, \text{tot}}}{\sum K_{\text{eff}, i}} \end{aligned} \quad (21)$$

The steps of the iterative procedure for the rigid deck model are as follows:

1. Selection of the bearings
2. Initial assumption for the displacement d_{bd}
3. Calculation of $K_{\text{eff}, \text{tot}}$, $\xi_{\text{eff}, \text{tot}}$ and $E_{D, \text{tot}}$ as a function of d_{bd}
4. Determination of the fundamental period of the equivalent system $T_{\text{eff}} = 2 \cdot \pi \cdot \sqrt{M_{\text{tot}}/K_{\text{eff}, \text{tot}}}$ where M_{tot} is the total mass
5. Determination of the seismic forces and the new displacement from Table 1
6. Repetition of steps 2–5 until converge of the displacements is achieved

Friction Pendulum Bearings (FPS)

Friction pendulum bearings constitute a variation of the spherical bearings, where the plane sliding top surface is replaced by a curved one (Fig. 21a, b). They exhibit, unlike spherical bearings, a re-centering capability and are not subjected to rotations. The force at zero displacement is provided by the friction and is given by

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Table 1 Seismic forces and design displacements (EN 1998-2 2005)

Fundamental period	Seismic forces	Design displacement
$T_C \leq T_{\text{eff, tot}} \leq T_D$	$F_{AE} = \beta \cdot \frac{T_C}{T_{\text{eff, tot}}} \cdot n \cdot A_g \cdot W$	$d_{bd} = \frac{T_{\text{eff, tot}}}{T_C} \cdot d_C$
$T_D < T_{\text{eff, tot}}$	$F_{AE} = \beta \cdot \frac{T_C \cdot T_D}{T_{\text{eff, tot}}^2} \cdot n \cdot A_g \cdot W$	$d_{bd} = \frac{T_D}{T_C} \cdot d_C$
Spectra	Acceleration spectrum	Displacement spectrum
		
Notation	A_g peak ground acceleration, W total weight, and $\eta = \sqrt{10/(5 + \xi_{\text{eff, tot}})} \geq 0.55$	

**Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 21** Layout of (a) single- and (b) double-friction pendulum bearings. (c) Force-displacement behavior of friction pendulum bearings

$$F_0 = \mu \cdot N \quad (22)$$

The kinematics of the bearings leads to following relations:

$$\sin \varphi = d/R \quad (23a)$$

$$\tan \varphi = F/N \quad (23b)$$

good approximation when $d/R \leq 0.25$ and considering the developing friction between surfaces, the following relation may be derived for the restoring force:

$$F = \frac{d \cdot N}{R} + \mu \cdot N \cdot \text{sign}(\dot{d}) \quad (24)$$

where:

Equating the above equations for small angles $\sin \varphi \approx \tan \varphi$ that may be considered as valid with N is the vertical force.

d is the horizontal displacement.

R is the radius of the spherical surface.

μ is the friction coefficient.

$\text{sign}(\dot{d})$ is the sign of the velocity.

It may be seen that the restoring force increases linearly with the displacement and the support reaction, i.e., with the mass. For two spherical surfaces, similar relations apply, where $R = R_1 + R_2$ (Fig. 21b).

Figure 21c displays the force-displacement characteristic of friction pendulum bearings that indicates a symmetrical response. The effective linear spring stiffness is proportional to the compression force and is determined from

$$K_{\text{eff}} = \frac{F}{d} = N \cdot \left(\frac{1}{R} + \frac{\mu}{d} \right) \quad (25)$$

The energy dissipation in a cycle is given by

$$E_D = 4 \cdot \mu \cdot N \cdot d \quad (26)$$

and the equivalent effective damping ratio by

$$\xi_{\text{eff}} = \frac{E_D}{2 \cdot \pi \cdot F \cdot d} = \frac{2 \cdot \mu}{\pi \cdot (d/R + \mu)} \quad (27)$$

When the rigid deck model is employed, the equivalent stiffness of all bearings is determined from

$$K_{\text{eff, tot}} = \sum K_{\text{eff, i}} = W_{\text{tot}} \cdot \left(\frac{1}{R} + \frac{\mu}{d} \right) \quad (28)$$

where the summation refers to all bearings i and W_{tot} is the total weight of the bridge in the seismic situation.

The individual spring stiffness for each bearing i is then

$$K_{\text{eff, i}} = \frac{N_i}{W_{\text{tot}}} \cdot K_{\text{eff, tot}} \quad (29)$$

where

N_i is the compression force of bearing i .

If bearings with identical radius R are selected, the damping ratios for each bearing

and for the overall system are equal to $\xi_{\text{eff, tot}} = \xi_{\text{eff, i}}$.

The steps of the iterative procedure for the rigid deck model are as follows:

1. Selection of the bearings, specifically the friction coefficient μ and the radius R
2. Initial assumption for the displacement d
3. Calculation of $K_{\text{eff, tot}}$ and $\xi_{\text{eff, tot}}$ as a function of d
4. Determination of the fundamental period of the equivalent system
 $T_{\text{eff}} = 2 \cdot \pi \cdot \sqrt{M_{\text{tot}}/K_{\text{eff, tot}}}$, where M_{tot} is the total mass
5. Determination of the seismic forces and the new displacement from Table 1
6. Repetition of steps 2–5 until converge of the displacements is achieved

The equivalent spring stiffness and energy dissipation may then be calculated for each individual bearing.

Fixed Bearings

Until the 1950s, steel bearings were used that consisted of four types: *pins*, *rollers*, *rockers*, and *metal sliding bearings*. Pins are fixed bearings allowing rotations. Rollers and rockers allow translation and rotation, while sliding bearings utilize one plane metal plate sliding against another, with PTFE as intermediate lubricant material, to accommodate translations. These older bearing types are modeled as hinges (see Fig. 22). Fixed bearings may also be represented by springs, their flexibility resulting from the flexibility of the bearing bars and the elongation of the anchor bolts.

The stiffness in longitudinal direction of fixed bearings may be determined from

$$\frac{1}{K} = \frac{h^3}{3 \cdot E \cdot I} + \frac{h \cdot l_b}{E \cdot A \cdot \sum_1^4 l_i} \quad (30)$$

where:

E is the modulus of elasticity for steel.

I is the second moment of area of the bearing bar ($I = b^3 \cdot h/12$).

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 22 Fixed bearing

h is the height of the bearing bar.

A is the area of the anchor bolts.

l_b is the length of the anchor bolts.

l_i are the distances of the anchor bolts from the tip of the base plate.

The stiffness in transverse direction is given by a similar equation, neglecting the first term due to the high stiffness of the bearing bar in this direction and changing the direction of the lengths l_i . If a bearing set is going to be represented by one translational and one rotational spring, the relevant spring stiffness may be expressed by

$$K_{hor} = \sum_1^n K_i \quad (31a)$$

and

$$K_{rot} = \sum_1^n K_i \cdot l_{bi}^2 \quad (31b)$$

where:

K_i is the stiffness of each bearing as determined before.

n is the number of bearings in the set.

l_{bi} is the distance of bearing i to the centerline of the bridge deck.

Modeling of Piers

Piers are generally represented by means of 6 DOF beam elements. The pier is usually

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 23 Representation of piers through discrete beam mass models – pier with (a) constant and (b) variable dimensions

subdivided in more elements, especially if its cross section varies along the height. The cross section of each element corresponds to the average pier section within its length (Fig. 23).

In frame bridges the superstructure runs continuously and is rigidly connected to the piers so that bearings and expansion joints are avoided. Such bridges are allowed to behave nonlinear in the seismic situation. Unlike in moment-resisting frame buildings where plastic hinges are developing in the beams, plastic hinges are expected to develop in bridges in the piers so that the superstructure behaves elastic (Fig. 24).

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 24 Plastic hinges in frame bridges

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 25 (a) End connection of superstructure to abutments in integral bridges. (b) Numerical grillage model of the end region of integral bridges

Accordingly for nonlinear analyses, the nonlinear properties of the piers shall be modeled. Two types of models may be used:

- (a) **Plastic hinge models:** The nonlinear behavior of the pier elements is located in rotational springs at the ends of the elastic behavior part of the element. The characterization of a plastic hinge requires a moment-curvature diagram to be defined. This is obtained from the cross-sectional response to monotonic loading that is derived from a finite element analysis.
- (b) **Plastic zone models:** This accounts for spread-of-plasticity effects in sections and along the beam-column element. Beam-column finite fiber elements may be used that are able to better characterize reinforced concrete elements. Consequently, higher accuracy in the structural damage estimate is attained, even for the case of high inelasticity levels.

A structural model that includes nonlinearity in a distributed fashion, using finite fiber elements, is able to characterize in higher detail the reinforced concrete elements and thought to capture more accurately response effects on such elements. Geometrical and material properties are the only required ones as input.

Modeling of Integral Bridges

Integral bridges are those where the steel girders are encased in the abutment walls so that bearings and expansion joints are avoided (Fig. 25a). Steel girders are connected to the abutment through reinforcement that passes through their web and by shear studs in the flanges or the web. Movements of the bridge due to thermal actions or time-dependent deformations of concrete are accommodated by the flexibility of piles that

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling,

Fig. 26 Finite element model of a filler deck bridge

support the abutments. To increase the support flexibility, steel piles are oriented with their flanges parallel to the girders so that bending occurs around their weak axis. Integral bridges are allowed for straight and skewed bridges but not for curved bridges. Settlements of the backfill are accommodated by an approach slab. Integral bridges exhibit a good seismic performance due to increased redundancy, smaller displacements, and larger damping due to nonlinear soil-pile-structure interaction.

A grillage model for the end region of integral bridges is illustrated in Fig. 25b. Steel girders and piles are represented by 6 DOF beam elements. Beam elements representing the girders are assigned the properties of the cracked composite cross section due to the fact that negative moments develop in abutment so that the concrete slab is in tension. This section includes the section of the steel girder and the reinforcement within the effective width. Due to the small distance between piles, the pile cap is supposed to be rigid so that piles are connected with horizontal rigid elements and not with beam elements. The connection of the embedded girder and the abutment is supposed to be rigid. Accordingly the beam elements of the girders are connected by vertical rigid elements with the pile cap. Finally, horizontal rigid elements are connecting the beam elements of the girders. The vertical pile support is supposed to be hinged. Springs in two horizontal directions represent the soil that supports the piles, with stiffness varying in depth.

Horizontal springs in the longitudinal direction represent the soil-passive pressure behind the abutment.

When nonlinear methods of analysis are employed, the soil springs and the beam elements of the piles are assigned nonlinear properties. In an extension of the model, the connection between girders and abutment is considered flexible so that compression-only springs are introduced at the contact points between girders and concrete material.

Modeling of Filler Deck Bridges

Filler beam where small distanced steel beams are encased in concrete are small span bridges and are used both as simply supported (max. span ≈ 15 m) and continuous systems (max. span ≈ 30 m). Shear connection is ensured by transverse reinforcement that passes through holes at the webs of the steel beams. Figure 26 shows such a bridge that is composed of closely spaced longitudinal IPE girders resting on two transverse steel H-shaped (HEA section) girders that are supported by reinforced elastomeric bearings. The bridge is orthogonal but the road is skew.

The longitudinal elements are represented by beam elements their section being composed from the steel girder and the associated concrete embedment. The transverse H girders are also represented by beam elements with an HEA cross section. Shell finite elements represent the

Seismic Analysis of Steel and Composite Bridges: Numerical Modeling, Fig. 27 Time history analysis of 2×34 m long span plate girder bridge with a 3D beam model

concrete slab that serve for an easy application of traffic loads, distribute vertical and horizontal loading between longitudinal beams, and ensure diaphragm action. In order to correctly represent the stiffness of the deck, the concrete of the longitudinal beam elements is assigned a very

low modulus of elasticity. However, concrete strength is introduced with its design value in order to allow correct design of the composite action. Deflections are calculated as average values between uncracked and cracked analysis, the latter being simulated by considering the

thickness of the concrete shell elements not as the total slab thickness but as the thickness of the compression zone. Bearings are represented by linear springs. The above-described model is a combination of a grillage and a FEM shell element model.

Application: Time History Analysis with a 3D Beam Model

A time history analysis of a two-span composite bridge with six main girders is indicatively demonstrated in Fig. 27. The bridge has been modeled according to the recommendations of the section “3D Models.” The superstructure rests on low-damping elastomeric bearings whose stiffness has been estimated through Eqs. 8, 9, 10, and 11a and 11b. For the analysis a damping factor equal to 2 % for the three first natural modes has been implemented, value taken from the fabricator of the bearings. The mass of the superstructure includes all the permanent loads and 20 % of the traffic loads. One can see that with the 3D beam model, the time variation of the vertical reaction forces R_z can be calculated; such a calculation with a grillage model would not be feasible. Moreover, the internal forces of the cross girders are calculated. Not only the grillage model but a detailed FE model as well would not give the possibility of such a calculation since shell or volume elements offer stresses and not forces or bending moments as final results. With the 3D beam model, the frame action of the cross girders (HEB 300) and the transverse stiffeners (1/2 HEA 400) could be adequately investigated.

Summary

Different types of models are used for the design and seismic analysis of steel and steel-concrete composite bridges. In this entry 1D, grillage, spine, 3D beam, and finite element models are presented. The advantages and drawbacks of each model are debated, and modeling

recommendations for plate, filler deck, and box girder bridges are provided. The implementation of structural bearings in the models is also discussed, and guidance on the calculation of the bearings’ stiffness and the seismic forces is given. The entry ends with an example of a time history analysis of a continuous composite beam and the calculation of reaction forces and displacements.

Synonyms

Numerical simulation of steel buildings; Structural design of steel buildings in seismic regions

Introduction

The aim of this contribution is to present the state of the art in numerical modeling of steel buildings, aiming at their structural analysis and design. To that effect, the successive stages of this process will be presented, including the conceptual design, numerical modeling, application of support conditions and loads, structural analysis, and design checks. The two latter issues, structural analysis and design checks, will be discussed briefly, to the extent that they interact with the modeling process, as they are also covered in detail in other parts of this encyclopedia. The interaction with other engineering disciplines throughout the design process will be demonstrated. For the purpose of this presentation, a prototype building will be used, which is described in the next section.

Description of Prototype Building

A simple single-story laboratory building, part of an industrial project, will be used as prototype building for this presentation. The building's plan view is 28.00 m by 15.00 m (Fig. 1), and there is a small loft in part of the building (Fig. 2). The roof is double pitched with minimum required clearance equal to 4.50 m (Fig. 3). The locations of exterior doors are fixed, imposing restrictions on

the layout of structural elements, as will be described in the following section. The preliminary architectural drawings include proposed column locations, indicated by their I-sections in the plan views of Figs. 1 and 2.

Conceptual Design

The initial stage of the structural design process consists of the so-called conceptual design, in which the different structural elements that are needed to support the structure are selected and are geometrically defined, taking into account the architectural requirements. In parallel, all restrictions imposed by the building's use, as well as its location and associated environmental actions have to be satisfied.

To that effect, close cooperation and interaction of the structural engineer with other involved engineering disciplines are necessary. Such disciplines include, at a minimum:

- The architectural engineering team, to determine the overall geometry; positions of openings; types of materials for floors, cladding, etc.; and associated dead loads and, in general, to ensure that structural choices do not interfere with the building's desired function and aesthetics
- The mechanical/electrical/HVAC engineering team, to determine loads that are associated with these functions of the building and to prevent conflicts with required shafts and other openings for passage of lifelines
- The geotechnical engineering team, to obtain data about the soil and its mechanical properties and to determine the type of the building's foundation

In conceptual design, all basic decisions, regarding material properties, structural system, loads, and codes to be applied, are taken. All structural engineering experts agree that this is the most important design stage and that these decisions affect significantly the project's design and construction schedule and

Seismic Analysis of Steel Buildings: Numerical Modeling, Fig. 1 Architectural plan view of ground floor of prototype building (out of scale)

FIRST FLOOR PLAN

Seismic Analysis of Steel Buildings: Numerical Modeling, Fig. 2 Architectural plan view of loft of prototype building (out of scale)

cost, sometimes even its feasibility. This is a process mostly dictated by the available experience of all participating design teams but can nowadays be assisted by modern software

tools, both for preliminary design of the different building’s facilities but also for communication between involved teams (building information modeling, BIM). However, a

Seismic Analysis of Steel Buildings: Numerical Modeling,

Fig. 3 Transverse section A-A of prototype building (out of scale)

Seismic Analysis of Steel Buildings: Numerical Modeling, Fig. 4 3D view of prototype building's 3D model

more detailed treatment of this design stage is beyond the scope of this presentation.

Several conceptual design choices for the prototype building described in section “[Description of Prototype Building](#)” are illustrated in Figs. 4, 5, 6, 7, 8, 9, 10, and 11. The figures have been obtained from a 3D model of the building's structure, made with a specialized modeling software, which enables integration of architectural and structural engineering and other solutions and production planning systems, working for both detailing and producing steel structures of any type.

The building's structural system consists of:

- Two-span main frames spaced at 6.00 m (with the exception of the first span, which is equal to 4.00 m) in accordance with the architectural proposal. Columns and girders have I-section, oriented so that the strong axis acts for in-plane loading. It is noted that a 6.00 m distance between main frames is optimum for avoiding loss of material in purlins and longitudinal beams, taking into account that steel members are commonly fabricated in 12.00 m lengths. Haunches are provided between

Seismic Analysis of Steel Buildings: Numerical Modeling, Fig. 5 Plan view of prototype building's 3D model above foundation level

Seismic Analysis of Steel Buildings: Numerical Modeling, Fig. 6 Plan view of prototype building's 3D model above loft level

columns and girders at internal frames, in order to achieve reduction of girder cross section and to accommodate the required number of bolts for a moment connection. External frames are equipped with vertical X-bracing, so that truss action dominates rather than frame action. As a result, smaller column and girder sections are possible, and there is no need for haunches between columns and girders.

- Longitudinal beams connecting the main frames at the top and at mid-height of columns. On one side of the building, the mid-height head beam is eliminated in the last span, to accommodate a required door at that location. A beam over the door is used instead. It is noted that this is not an optimum structural configuration, but it is an acceptable compromise to respect functional requirements.

Seismic Analysis of Steel Buildings: Numerical Modeling, Fig. 11 Transverse section of prototype building's 3D model at spans without loft

- Vertical X-bracing at two spans to provide lateral stability in the longitudinal direction. The type of bracing depends on panel geometry, aiming at inclination that is as close as possible to 45° .
- Horizontal roof bracing at the same spans where vertical bracing is provided, as well as

at the roof's peripheral panels, to ensure sufficient diaphragm action.

- Roof and side purlins to support cladding.

A peripheral reinforced concrete wall is provided, to ensure water tightness and to protect the steel columns from eventual vehicle collisions.

Taking also into account the available geotechnical information for this site, foundation beams are provided at the periphery of the building, along the axis of intermediate columns and below the auxiliary columns supporting the loft. A steel staircase is provided to connect the ground floor with the loft.

Numerical Modeling

For the simulation, analysis and design of superstructure and foundation use is made of an appropriate finite element software. Views of the finite element model are shown in Figs. 12, 13, 14, and 15.

Seismic Analysis of Steel Buildings: Numerical Modeling, Fig. 12 3D view of prototype building's finite element model

Seismic Analysis of Steel Buildings: Numerical Modeling, Fig. 13 Foundation plan view from prototype building's finite element model

Seismic Analysis of Steel Buildings: Numerical Modeling, Fig. 14 Loft's plan view from prototype building's finite element model

Seismic Analysis of Steel Buildings: Numerical Modeling, Fig. 15 Roof's plan view from prototype building's finite element model

Some recommendations of good practice when setting up the finite element model are the following:

- It is recommended not to include roof and side purlins and other secondary members in the numerical model. The type of connection between purlins and main frame, which is a simple support so that both purlins and frame

columns and girders are continuous but do not transmit moments to each other, would require rigid links for correct modeling, which is possible in most structural programs, but would render the model unnecessarily complex. Only those members that have an active role in the building's spatial response to either vertical or horizontal actions need to be modeled. Other members can be modeled, analyzed, and

Seismic Analysis of Steel Buildings: Numerical Modeling,

Fig. 16 Column base connections of prototype building, modeled as hinges

dimensioned independently, and the loads they transfer to the frames can be applied directly upon the frame columns and girders in the 3D finite element model.

- Haunches can be modeled by means of uniform beam section over the entire length of the haunch, usually the one at haunch mid-length. This provides a satisfactory representation of increased girder stiffness in the area of the haunch and enables safe prediction of strength for the design phase.
- Particular attention is needed for the appropriate modeling of supports and connections, by releasing the appropriate member degrees of freedom depending on the connection detail. Even though real connections between steel members are neither perfect hinges nor perfect moment connections, it is common practice to model all connections as either hinges or moment connections, at least initially. Modern codes provide tools for eventually classifying connections as semirigid (e.g., European Committee for Standardisation 2003c), in which case either the connections should be stiffened to become rigid or a rotational spring should be inserted in the model to represent the partially restricted connection between the members in question. The decision about the type of joint to be included in the model depends mainly on the lever arm between bolts in the connection. Connections of I-beams where all bolts are between the

flanges are commonly modeled as hinged, as is the case with the supports of all columns in the prototype building (Fig. 16). In case bolts are provided outside the flanges, rigid moment connections are considered in the model, as is the case with the column to girder connections in the prototype building (Fig. 17). Welded connections are usually modeled as rigid, while connections between or at the end of bracing members (Fig. 18) are modeled as hinged.

For moment connections, no intervention is required in the model, as this is the default option for frame structures. Hinged connections are modeled by means of releases of appropriate rotational degrees of freedom at the members' ends. In Figs. 19 and 20, moment releases at the ends of roof and vertical bracing as well as secondary beams are denoted by black dots.

- If there is a diaphragm in the structure, as, for example, is the case with the composite slab of the loft in the prototype building, it is recommended to avoid the more complex option of modeling it with shell elements and instead create a "master" node that will be connected with all nodes of the diaphragm (Fig. 21). In this case, in order to account for uncertainties in the location of masses and in the spatial variation of the seismic motion, the calculated center of mass at each floor shall be considered as being displaced from its

nominal location in each direction by an accidental eccentricity, commonly taken equal to $e = 0.05 \cdot L$, where L is the corresponding span length.

Loads

The next phase of the design process consists of setting up appropriate loading situations including basic loads and load combinations. Basic loads commonly include permanent loads, live loads depending on the building's intended use,

and environmental loads such as those due to snow, wind, and temperature, as well as seismic actions in case the building is located in a seismic region. Characteristic nominal values of live, snow, and wind loads and seismic actions are prescribed by pertinent codes (e.g., European Committee for Standardisation 2001b, 2003a, b, d, 2004a).

For the prototype building presented here, Excel spreadsheets for the calculation of snow, wind, and seismic loads are illustrated in Figs. 22, 23, 24, and 25. Issues that may require special attention include snow accumulation due

Seismic Analysis of Steel Buildings: Numerical Modeling, Fig. 22 Excel spreadsheet for snow load calculation for the prototype building according to Eurocode 1 – Part 1–3

to roof geometry, increased snow density in regions of low temperatures, or unusual building shapes not covered by the code guidelines for wind loads. Choices that differentiate the design spectrum of steel structures from those of structures made of different materials are the values of damping, commonly taken equal to 2 % for welded and 4 % for bolted steel structures, and

the values of behavior factor, for which recommendations are provided in the pertinent seismic codes, depending also on the type of structural system.

In case part of the structure is buried (e.g., a basement), it is recommended to define accordingly the level above which the structure vibrates independently of the ground.

Seismic Analysis of Steel Buildings: Numerical Modeling, Fig. 23 Excel spreadsheet for wind load calculation on the side walls of the prototype building according to Eurocode 1 – Part 1–4

Seismic Analysis of Steel Buildings: Numerical Modeling, Fig. 24 Excel spreadsheet for wind load calculation on the roof of the prototype building according to Eurocode 1 – Part 1–4

Following load calculation, basic loads are then applied on the model, as shown schematically in Figs. 26, 27, 28, and 29.

The next step is to describe pertinent load combinations in accordance with the relevant codes (e.g., European Committee for Standardisation 2001a), including combinations in the ultimate (ULS), serviceability (SLS), and seismic limit states. Common load combinations

for ordinary steel buildings are provided in Table 1.

In Table 1:

- Live load corresponds to all relevant types of live load, such as service load or load due to snow.
- Wind load corresponds to four basic individual load cases for each direction, including

Seismic Analysis of Steel Buildings: Numerical Modeling,

Fig. 25 Horizontal component of elastic response spectrum of the prototype building according to Eurocode 8

Seismic Analysis of Steel Buildings: Numerical Modeling,

Fig. 26 Application of dead loads on the finite element model of the prototype building

S

uplift or downward pressure on the roof and positive or negative pressures on the walls.

- Earthquake load corresponds to three basic individual load cases, one for each global direction.
- Temperature load corresponds to two basic individual loads (increase, decrease).

Structural Analysis

A decision that has to be taken next concerns the type of structural analysis to be performed.

A variety of linear and nonlinear (geometrically and/or material) and static or dynamic analysis algorithms are commonly available in commercial structural software (e.g., Gantes and Fragkopoulos 2010). However, in the vast majority of common steel buildings, linear static analysis is used in design practice for all loads and load combinations, with the exception of seismic actions, for which frequently both equivalent static as well as response spectrum dynamic analysis are carried out. The principle of

Seismic Analysis of Steel Buildings: Numerical Modeling,

Fig. 27 Application of live loads on the finite element model of the prototype building

Seismic Analysis of Steel Buildings: Numerical Modeling,

Fig. 28 Application of wind loads on the finite element model of the prototype building

superposition is routinely employed to obtain action effects for load combinations.

In the equivalent static method, first the base shear is calculated, which is then distributed over the height of the building as specified by the pertinent seismic code. In the response spectrum analysis, for a given direction of acceleration, the

maximum displacements, forces, and stresses are computed throughout the structure for each vibration mode. These modal values for a given response quantity (displacements, forces, or stresses) are then combined appropriately to produce a single, positive result for the given direction of acceleration, using, for example, the SRSS

Seismic Analysis of Steel Buildings: Numerical Modeling, Fig. 29 Application of temperature increase on the finite element model of the prototype building

or the CQC method. It is noted that most modern codes contain a requirement of modal participating mass ratios at least equal to 90 %. In case this is not satisfied, the response spectrum analysis must be repeated with higher number of participating modes.

The analysis results include mode shapes and natural periods of vibration as well as deformed shapes and internal force diagrams for all individual loads and load combinations. A qualitative evaluation of analysis results is always highly recommended in order to detect possible modeling errors. For that purpose, it is a good practice to start with mode shapes and natural periods of vibration, proceed with deformed shapes for individual load cases, continue with internal force diagrams for individual load cases, and finally, conclude with internal force diagrams for load combinations and envelopes, which are also

used for design. Indicative results for the prototype building are presented in the following figures, including mode shapes (Figs. 30 and 31), seismic deformed shapes (Figs. 32 and 33), and internal force diagrams for individual load cases (Fig. 34) and load combination envelopes (Figs. 35, 36, 37, and 38).

Structural Design Checks

Following the qualitative evaluation of analysis results on the basis of mode shapes and corresponding vibration periods, deformed shapes and internal force diagrams, and provided that confidence is gained for the correctness of these results, design checks are performed, consisting of general checks, member checks, and connection checks. Foundation checks are

S

also part of this process, which are presented in other parts of this encyclopedia. This is an iterative process, and frequently, there is a need to return to the model, modify it, and run a new set of analyses and checks, as schematically illustrated in Fig. 39.

General checks (e.g., European Committee for Standardisation 2004b) consist mainly of confirming that overall structure deformations

are acceptable for all load combinations. This includes interstory drifts and overall building drift for all load combinations with predominantly horizontal components, such as wind and seismic combinations. Depending on the use of the building, general checks may also include restrictions about the vertical vibration frequencies, associated with a sensation of unease of the users, as is the case in stadium grandstands. In case such checks

Seismic Analysis of Steel Buildings: Numerical Modeling,

Fig. 33 Deformed shape of prototype building from equivalent static method – longitudinal direction

Seismic Analysis of Steel Buildings: Numerical Modeling,

Fig. 34 Moment M_3 diagrams of prototype building from equivalent static method – seismic action in transverse direction

are violated by far, a modification of the structural system may be the only solution, while smaller violations may be addressed by increasing member cross sections.

Member checks (e.g., European Committee for Standardisation [2004b](#)) consist of comparison between actions and resistances in the ultimate limit state and comparison of

maximum deflections to allowable upper bounds in the serviceability limit state. As flexural and lateral-torsional buckling are in most cases critical for steel members, it is highly recommended that the engineer reviews and modifies as needed the buckling lengths initially proposed by the software for the corresponding checks. It is also

Seismic Analysis of Steel Buildings: Numerical Modeling,

**Seismic Analysis of Steel Buildings: Numerical Modeling,**

Fig. 36 Envelope of moment M_2 diagrams of prototype building for ULS combinations

S

noted that most seismic design codes require capacity design checks, leading, for example, to the necessity of larger bracing sections to satisfy minimum slenderness requirements or larger column sections, to adhere to the weak beam-strong column design approach.

Connection checks (e.g., European Committee for Standardisation 2003c) include strength checks, to ensure safe transfer of internal actions between members, as well as stiffness checks, so that the behavior of actual connections (Fig. 40) is in accordance with the hinged/semirigid/rigid assumptions adopted in

Seismic Analysis of Steel Buildings: Numerical Modeling,

Fig. 37 Envelope of shear V_2 diagrams of prototype building for ULS combinations

**Seismic Analysis of Steel Buildings: Numerical Modeling,**

Fig. 38 Envelope of axial force N diagrams of prototype building for ULS combinations

the numerical simulation. As there is so far limited experience with the behavior of semi-rigid connections under cyclic loading, it is recommended to avoid their use in seismic regions. Instead, it is proposed to stiffen the connection so that it can be classified as rigid. Strength calculation and stiffness classification of steel connections are commonly performed by means of dedicated software.

Foundation checks depend on the type of foundation (mat foundation, foundation beams, spread footings, pile foundation, etc.) and consist of general stability checks (overturning, sliding), soil bearing capacity checks, comparison of absolute and differential settlements to allowable values, and calculation of reinforcement for the reinforced concrete elements.

Summary

The state of the art in numerical modeling of steel buildings has been presented, from the point of view of the practicing structural engineer designing such structures in seismic regions.

Conceptual design, numerical modeling, structural analysis, and design checks have been discussed, but emphasis has been directed toward modeling, as the other design phases are covered in detail in other parts of this encyclopedia.

Introduction

Steel–Concrete Composite (SCC) Systems

Composite construction includes a wide range of structural systems, e.g., framed structures employing all steel–concrete composite (SCC) members and components (e.g., composite beam-to-columns and connections) and sub-assemblages of steel and/or reinforced concrete (RC) elements. Such components and elements are employed to optimize the resistance and deformation capacity (Uchida and Tohki 1997). SCC structures have been used

extensively in recent years because of benefits in combining the two construction materials. SCC structures are also known for their excellent earthquake performance owing to their high strength, high ductility, and large energy absorption. Their good structural damping properties arising from the friction between the steel–concrete interfaces make them an even more attractive alternative for seismic resistance.

Consequent effects of combining the two materials are the enhanced lateral strength and stiffness of the frame, with apparent effects of the alteration of the structural natural period of vibration and the complex local behavior of beam-to-column connections. Furthermore, SCC beams subjected to lateral loading show complex behavior due to several factors, including the slip between the concrete slab and the steel beam, the variation of longitudinal stress across the width of the slab, and the overall configuration of the numerous different types of models, while the steel and concrete parts can be subjected to different actions in every case. For the above reasons, the calculation of the seismic response of composite structures is not a straightforward task due to the interaction of local and global effects and hence the unexpected failure modes that might incur. Consequently, it is very important for the analysis of such structures to account for the local interactions (e.g., interface behavior between steel and concrete) as well as the local behavior of structural systems (e.g., beam-to-column and base-to-column response). All these factors make the analysis of SCC structures and their individual components an intriguing but challenging task.

Although experimental procedures can be performed in order to enhance the understanding of the behavior of SCC structures under earthquake loading, they are typically expensive and time-consuming and do not cover a broad range of SCC structures and elements. As a result, numerical modeling procedures have been developed and tested in order to facilitate the analysis of such structures.

Most finite element (FE) packages (e.g., ANSYS, ABAQUS, ADINA, DIANA, LS-DYNA, MIDAS FEA, etc.) rely on the use of

constitutive models which emphasize on the description of post-peak material characteristics such as strain hardening and softening, tension stiffening, shear-retention ability, etc. (Cotsovos and Kotsovos 2011). The derivation of such constitutive models has been based on a variety of theories and their combination. However, the application of FE packages in practical structural analysis has shown that the constitutive relationships are case-study dependent, since the solutions obtained are realistic only for particular problems. Therefore, the applicability of packages to a different set of problems requires modifications of the constitutive relationships. This is entirely dependent on the interpretation of the observed material behavior as well as the use of the experimental data to validate the constitutive relationships.

To this end, the aim of the present chapter is to provide an indication of the concepts which are widely used for modeling the steel–concrete composite behavior and to develop numerical guidelines for the nonlinear analysis of such structures and their components, considering the seismic actions under earthquake events. The numerical analyses presented herein model the behavior of SCC structures/components using macro-models (i.e., the use of line elements and spring connections) rather than micro-models (continuum FE models) due to their simplicity and accuracy in nonlinear analysis. Different aspects of modeling including the geometry, material nonlinearity (through the constitutive laws adopted), hysteretic behavior, and geometrical nonlinearity as well as other parameters important for seismic analysis are also presented in this chapter.

Chapter Synthesis

The modeling of SCC elements and frames is based on three approaches. The first one is the simplified modeling approach presented in this chapter, engaging the use of springs and line elements for the elementary simulation of the behavior of each component to the entire frame assembly. The scope is to initiate numerical guidelines based on the simplified approach and to present modeling examples of SCC beam cross sections, flooring systems, fully composite

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling, Chart 1 Structure of the Chapter

members, beam-to-column connections, as well as holistic approaches modeling a frame. The breakdown of this chapter is given in Chart 1.

Based on the bottom-up approach (i.e., combining different structural components starting from the most fundamental of a system and giving rise to grander systems), the engineer will gain a decent understanding on the parameters to be considered during the computational modeling procedure. Modeling of these structural components will enable the computation of their response to different load histories and moreover will enable the engineer to carry out the state determination of a member from a frame assembly.

Requirements for Collapse Analysis of Composite Structures

Numerical modeling procedures should aim to address a number of issues regarding the local, intermediate, and global level of SCC structural design. On the *local* level, aspects such as the cyclic behavior of the steel and the concrete members (including the softening and hardening of the material), the local buckling of steel flanges, the load carrying capacity, the curvature ductility of the components, as well as the effects of

confinement should be carefully studied. On the *intermediate* level, the ductility of the member in terms of rotation/displacement should be established. Additionally, second-order effects ($P-\Delta$) on forces and deformations should be taken into account through the provisions for large displacement analysis. Modeling the beam-to-column connection is also essential when the fully rigid assumption is not suitable. On the *global* level, the overall ductility and strength of the structure should be established through force–displacement relations. The progressive yielding and the hinge formation at the structural frame should also be established through moment–rotation relationships. The complete list of requirements for the collapse analysis and the modeling of SCC structures subjected to earthquake actions is presented below:

- Stress–strain relationships for the steel material including strain hardening and softening
- Provision for the effects of local buckling in the steel section
- Stress–strain relationships for the concrete material including cycling loading regimes and the effect of the confinement on the peak stress and corresponding strain

- Explicit representation of the slip boundary conditions of the shear connection both at local and global levels
- Provision for second-order effects on forces and deformations
- Effective beam-to-column connection models, including panel distortion
- Iterative and advanced dynamic analysis techniques for analyzing the structural response near collapse state

Modeling of Steel–Concrete Composite (SCC) Beams

A variety of different models have been developed by researchers in order to capture the behavior of SCC beams, based on either concentrated or distributed plasticity. In concentrated plasticity models, all the inelasticity is concentrated at the ends of the member; therefore, it deals with material nonlinearity in an approximate but efficient manner. On the contrary, distributed plasticity models simulate the inelastic behavior along the length of the member. This approach is more accurate but at the same time is more computationally demanding. Most of the formulations for both approaches are rather complex and not amenable to generic and routine application in structural engineering design.

The present subchapter presents a simplified (new) modeling approach based on the work of Zhao et al. (2012) for the nonlinear analysis of SCC beams and composite frames with deformable shear connections (based on the distributed plasticity approach) using line elements to simulate the structural beam and column members, layered fiber section to simulate the reinforced concrete slabs, and nonlinear spring elements for the simulation of the interface between the structural steel beams and the reinforced concrete slab. Vertical interactions between the slab and steel beams are not expected to be significant, therefore are not accounted into the analysis. The geometry of the model, along with a simple set of details, is outlined below. The assembled model is shown in Fig. 1.

Model Geometry of a Typical SCC Beam

To model the geometry of the macromodel for a typical SCC beam, the following assemblies should be utilized:

1. Four-node-layered shell elements representing the concrete slab. Reinforcement layers comprising steel material properties should be used to simulate the steel reinforcement located at the top and bottom of the concrete slab.
2. Two-node fiber beam-to-column elements for modeling the steel beam. The reference surface of the slab will be located at the centroid of the steel beam cross section.
3. Dummy nodes at the same locations as the beam-to-column element nodes simulating the connection between the nodes of the steel beam and the shell elements.
4. Rigid beam elements connecting the dummy nodes and the corresponding ones of the shell elements, located on the same x- and z-coordinates.
5. Discrete spring elements with only translation in the z-direction connecting both the dummy nodes and the beam-to-column element nodes in order to control the interface shear-slip surface along the length of the beam.

Model Geometry of Beam with Deformable Shear Connection

Modeling of two-dimensional beams with deformable shear connection is based on the Newmark et al. (1951) model, in which (i) the Euler–Bernoulli beam theory applies to both components of the SCC beam and (ii) the deformable shear connection is represented by an interface model with distributed bond allowing interlayer slip as well as enforcing contact between the steel and concrete components.

A local coordinate system should be established to enhance the understanding of kinematics of Newmark’s model. With reference to Fig. 2, Z axis is parallel to the beam axis and the vertical plane YZ is the plane of geometrical and

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling, Fig. 1 Assembled macromodel representing a typical steel-concrete composite beam

material symmetry of the cross section. Loads are also assumed symmetric with respect to the YZ plane. The displacement field u of a material point of the beam is given by:

$$u(y, z) = v(z)j + \left[w_a + (y_a - y)v'(z) \right]k \quad \text{on } A_a (a = 1, 2) \quad (1)$$

where w_a is the axial displacement of the reference point of domain A_a , the ordinate of which is y_a ($a = 1$: concrete slab, $a = 2$: steel beam); v is the vertical displacement of the cross section; and j and k denote the unit vectors along the Y and Z axes, respectively. It is observed that the transverse displacements and rotations of the slab and of the steel beam are equal due to the enforced contact between the two components. The only nonzero strain components are the axial strain ϵ_{za} and the interface slip δ :

$$\epsilon_{za}(y, z) = w'_a(z) + (y_a - y)v''(z) \quad \text{on } A_a (a = 1, 2) \quad (2)$$

$$\delta(z) = w_2(z) - w_1(z) + hv'(z) \quad (3)$$

where $h = y_2 - y_1$ is the distance between the reference points (G_1 and G_2 in Fig. 2) of the two components. At the locations of the longitudinal reinforcement, Eq. 2 also provides the strain in the reinforcement, due to the assumption of perfect bond between the steel and the concrete.

FE Formulations

A simple two-dimensional 10 degree-of-freedom (DOF) SCC frame element with deformable shear connection is presented herein, similarly to Zona et al. (2008). With reference to Fig. 3, 8 of the 10DOFs are external (4 DOFs per end node) allowing for the axial displacement, the transverse displacement, and the rotation of the steel beam and 1DOF for the axial displacement

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling, Fig. 2 Kinematics of two-dimensional composite beam model and reference system

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling, Fig. 3 10DOF SCC beam element used (a) references defined at the beam and slab centroids and (b) references defined at the slab–beam interface

of the concrete slab. The remaining internal 2DOFs allow for axial displacement of the steel beam and the concrete slab (Fig. 3b).

Modeling of Inertia and Damping Properties

Modeling the inertia properties of the frame elements can be achieved using lumped masses at the DOFs of the external nodes. Consequently, the inertia properties of the FE model are independent of the type of finite elements employed (i.e., the structure's mass matrix can be obtained using force, displacement, or mixed-based formulation frame elements).

Even though the friction between steel beams and concrete slabs in SCC frames may be a strong source of structural damping, quantitative information about this energy dissipating mechanism usually referred to as structural damping is limited owing to the partial availability of experimental dynamic data. Consequently, the well-known and widely used Rayleigh damping model can be used by the practicing engineer. In this model, the damping matrix can be obtained using the classical Rayleigh damping relationship (Eq. 4), where the damping matrix is proportional to the mass matrix and the initial stiffness matrix:

$$[C] = \mu[M] + \lambda[K] \quad (4)$$

where

μ = mass proportional Rayleigh damping coefficient

λ = stiffness proportional Rayleigh damping coefficient

M = system structural mass matrix

K = system structural stiffness matrix

Note: The proposed model presented in the above sections considers only rigid beam-to-column connections. Nevertheless, semirigid connections can be considered in the same numerical procedure by introducing special joint elements with prescribed constitutive behavior.

Constitutive Stress–Strain Relationships

For modeling purposes, the material properties (such as the Young's modulus, Poisson's ratio,

elastic and plastic strength, and strain hardening) can be obtained from the uniaxial stress–strain curves derived from coupon tests and then applied to the corresponding fibers across the composite cross section. In order to accurately simulate the behavior of SCC beams under earthquake conditions, robust material models capable of simulating the material nonlinearity as well as other damaging effects under dynamic or cyclic loading (i.e., softening/hardening) need to be employed. Several models have been developed to achieve the aforementioned scope, some of which are presented in the following sections.

Constitutive Law for Concrete Parts (Based on the Kent–Park Model)

The proposed constitutive law modeling the concrete in monotonic compression for the cases of confined and unconfined concrete is the Kent–Park model as described in Park and Paulay (1975). As it is shown in Fig. 4, the material follows a parabolic stress–strain curve up to a maximum stress equal to the cylinder's strength, after which it decays linearly with strain until the residual strength is reached. In tension, the model assumes a linear stress–strain behavior up until the tensile limit of the material is reached, and then the stiffness and strength decays with increasing strain (Fig. 5).

The cyclic behavior of the concrete can be described by the Blakeley–Park model also presented in Park and Paulay (1975). The stress–strain response lies within the Kent–Park envelope; however, the effect of concrete confinement is not taken into account. The model assumes that unloading and reloading takes place along a line without energy dissipation or stiffness deterioration for strains smaller or equal to the strain corresponding to peak stress ($\epsilon < \epsilon_c$). Beyond this point, the stiffness deterioration is taken into account through the introduction of reduction factors, given by Blakeley and Park. Along the first unloading branch, the stress is reduced approximately 50 % without any reduction in strain. The reloading branch with slope equal to $f_c E$ extends back to the envelope (Fig. 5).

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling, Fig. 4 Monotonic stress–strain Kent and Park model for unconfined and confined concrete

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling, Fig. 5 Cyclic stress–strain Blakeley–Park model for concrete

Constitutive Law for Concrete (Based on the Popovics–Saenz Law)

The constitutive law for concrete is a uniaxial cyclic law with monotonic envelope defined by the Popovics–Saenz law (Balan et al. 1997). Linear unloading–reloading branches with progressively degrading stiffness characterize the cyclic behavior of the material. The response of concrete under cyclic loading is shown in Fig. 6. According to the same figure, after each unloading–reloading, the monotonic envelope is reached again when the absolute value of the largest compressive strain attained so far is surpassed. The tensile behavior of concrete is characterized by the same loading–unloading–reloading rules with the same initial stiffness and appropriate values for the other parameters.

Constitutive Law for Steel

Figure 7a, b describes the elastoplastic response of the steel under monotonic and cyclic loading respectively. For monotonic loading, the characteristic yield plateau in the stress–strain model followed by a region of increased strength owing to strain hardening of the material. The unloading from the yielded condition is elastic; thereafter, the Bauschinger effect can be represented by a Ramberg–Osgood relationship (Eq. 5) until the yield stress is reached. This model uses a single nonlinear equation to characterize the observed curvilinear response of steel subjected to monotonic loading:

$$\varepsilon = \frac{\sigma}{E} + K \left(\frac{\sigma}{E} \right)^\eta \quad (5)$$

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling,

Fig. 6 Hysteretic concrete material model under compression

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling, Fig. 7 (a) Stress–strain model under monotonic loading. (b) Steady-state cyclic response of mild steel

where

$\frac{\sigma}{E}$ = equal to the elastic part of the strain
 $K\left(\frac{\sigma}{E}\right)^\eta$ = accounts for the plastic part of the strain
 K and η = parameters that describe the hardening behavior of the material

When the steel material is subjected to constant strain amplitude under cyclic loading, it exhibits a response that converges to a stabilized saturation loop which depends only on the cycling amplitude (Fig. 7b). As it is shown in Fig. 8, the response of the steel material under

constant strain amplitude cycles is described by strain hardening for large amplitudes and strain softening for small amplitudes. For the accurate simulation of the steel material response under an arbitrary load, the constitutive model needs to account for all the monotonic response, the steady-state cyclic behavior, as well as the transient behavior involving softening and hardening. This can be achieved using an efficient simplistic computationally bilinear model.

Bilinear Stress–Strain Steel Model In this bilinear model, the elastic range remains

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling,

Fig. 8 Cyclic response of steel under constant strain amplitude cycles

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling,

Fig. 9 Loading and unloading paths of bilinear kinematic model

constant throughout the various loading stages. The kinematic hardening rule for the yield surface is assumed to be a linear function of the increment of plastic strain

(Fig. 9). The calculation of the current stress state is expressed mathematically using Eqs. 6, 7, and 8, and it is presented graphically in Fig. 10:

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling, Fig. 10 Stress determination with the bilinear kinematic model

$$\left. \begin{aligned} \alpha &= \alpha^0 \\ \sigma &= \sigma^0 + E(\varepsilon - \varepsilon^0) \end{aligned} \right\} \quad (6)$$

If $\left(\frac{\alpha - \sigma_y - \sigma^0}{E} \right) \leq (\varepsilon - \varepsilon^0) \leq \left(\frac{\alpha^0 + \sigma_y - \sigma^0}{E} \right)$

$$\left. \begin{aligned} \alpha &= \alpha^0 + \mu E \left(\varepsilon - \varepsilon^0 - \frac{\alpha^0 + \sigma_y - \sigma^0}{E} \right) \\ \sigma &= \alpha + \sigma_y \end{aligned} \right\} \quad (7)$$

If $(\varepsilon - \varepsilon^0) > \left(\frac{\alpha^0 + \sigma_y - \sigma^0}{E} \right)$

$$\left. \begin{aligned} \alpha &= \alpha^0 + \mu E \left(\varepsilon - \varepsilon^0 - \frac{\alpha^0 - \sigma_y - \sigma^0}{E} \right) \\ \sigma &= \alpha - \sigma_y \end{aligned} \right\} \quad (8)$$

If $(\varepsilon - \varepsilon^0) < \left(\frac{\alpha^0 - \sigma_y - \sigma^0}{E} \right)$

where according to Figs. 9 and 10:

E = Young's modulus

μ = strain hardening parameter

σ_y = initial yield surface

ε = current strain

σ = current stress

α = current center of elastic range

Subscript "0" denotes values at the start of an increment

Constitutive Law for Steel (Based on the Menegotto–Pinto Model)

The constitutive law describing the behavior of the steel material is the uniaxial Menegotto–Pinto model (1973). This computationally efficient nonlinear law is capable to model both kinematic and isotropic hardening as well as the Bauschinger effect, allowing for accurate simulation and reproduction of experimental results. The response of the steel material is defined by the following nonlinear equation:

$$\sigma = b \varepsilon + \frac{(1 - b) \varepsilon}{(1 + \varepsilon^R)^{\frac{1}{R}}} \quad (9)$$

where the effective strain and stress (ε , σ) are a function of the unload–reload interval, b is the ratio of the initial to final tangent stiffness, and R defines the shape of the unloading–reloading curves. Figure 11 presents a typical stress–strain response based on the Menegotto–Pinto model. The model assumes a symmetric response for loading in compression and tension.

Interaction of Material Surfaces: Evaluation of Spring Properties

The degree of composite action and interaction between the steel beam and the concrete slab is a fundamental mechanism that needs to be

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling,

Fig. 11 Menegotto–Pinto material constitutive model for structural steel; typical cyclic stress–strain response

considered by the engineer during the modeling procedure of SCC beams and structural systems owing to the implications on the serviceability and ultimate limit states, the energy dissipation under cyclic loading, and the local stress distribution.

Two different modeling approaches can be used for the description of partial bond in SCC structural systems. The concentrated bond approach is based on the use of concentrated springs for the modeling of the connection. The springs are attached at the location of each connector, modeling either the action of the shear stud connectors between the steel and the concrete slab or the friction in concrete-filled hollow sections and partially encased steel sections. The second approach is based on the distributed bond model, which assumes a continuous bond stress and bond slip along the contact surface. For both approaches, the uplift is typically neglected; therefore, it is considered that the concrete slab and the steel beam have the same vertical displacement and curvature.

Shear–slip relationships are widely available providing information regarding the behavior of the connectors. Figure 12a presents a simplified bilinear shear–slip relationship based on a widely used shear–slip model proposed by Ollgaard et al. (1971). The Ollgaard model is described by the following exponential function (Eq. 10) representing an experimentally observed large reduction of stiffness with increasing slip:

$$\frac{N_v}{N_{vu}} = (1 - e^{-ns})^m \quad (10)$$

where

N_{vu} = connection (ultimate) strength

N_v = shear load

s = slip between two components of the composite beam (interface slip)

n, m = empirical parameters defining the shape of the curve calibrated from experimental data

In Fig. 12b, the monotonic envelope is presented by the definition of an ultimate slip, S_{ult} . When ultimate slip, the shear force–slip behavior follows zero stiffness with constant shear force $N_v = \pm \tau_{fr}$, where τ_{fr} is the residual shear force.

Modeling of Steel–Concrete Composite Beam-To-Column Partial-Strength Semirigid Connections

Compared to traditional bare steel structures, SCC frames can achieve more effective beam-to-column connections through the contribution of the concrete slab in resisting bending moments under gravitational and lateral loads. Additionally, these structures comprising partial-strength partially restrained beam-to-column joints designed in such a way to exhibit ductile seismic

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling, Fig. 12 Shear–slip relationships

response through the plastic deformation of their components can achieve the formation of a desirable beam hinging global frame mechanism, with large hysteretic energy dissipation capacity and reduced force demand on the columns.

This section of the chapter presents a simplified approach based on the work done by Braconi et al. (2007) for the nonlinear analysis of a partial-strength beam-to-column connection using a component model. The behavior of partial-strength beam-to-column connections under the application of seismic load is described using

nonlinear spring elements as shown in Fig. 13. With reference to the same figure, the elements comprising the model should account for the response of the:

1. Concrete in compression
2. Column web panel in shear
3. Upper T-stub in compression (+Ve moment)
4. Lower T-stub in tension (+Ve moment)
5. Concrete slab in tension
6. The shear studs (+Ve moment)
7. Upper T-stub in tension (–Ve moment)
8. Upper T-stub in compression (–Ve moment)
9. Shear studs (–Ve moment)

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling, Fig. 13 Component model: (a) overall joint model, (b) kinematics of the

concrete slab in compression (component 1), (c) kinematics of the concrete slab in tension (component 5), and (d) overall exterior joint model

Kinematics

Equilibrium must be maintained between the force acting in the nine components and the internal and external forces. The response of the assembled model is therefore defined by a set of eight equations related to translational equilibrium between components in the same beam-to-column connection, equilibrium between the shear studs and the beam steel profile, rotational equilibrium between the internal forces in the beam-to-column connection and the bending moment of the beam framing in it, as well as rotational and translation equilibrium acting on the column web panel. The set of eight equations can be then solved using a numerical procedure (i.e., Newton–Raphson) considering the storey deformation (drift, δ) as such an external action in the format of imposed deformations.

On the basis of the small displacement theory, the local kinematics could be described using a total of 7DOFs: the horizontal displacement of the bottom surface of the slab on both sides of the column, u_1 and u_2 ; the horizontal displacement of the top surface of the slab on both sides of the column, u_3 and u_4 ; the relative rotation of the two beams with respect to the column faces, θ_1 and θ_2 ; and the column panel zone shear distortion, γ . The deformations, δ , of the nine components

comprising the model are linked to the seven degrees of freedom through the following equations:

$$\delta_{1,i}^{nc} = -u_3 - \frac{\Delta_{nc}}{2} (2i - 1) \tan(\theta_1) + \left[h_{cs} - \frac{\Delta_{nc}}{2} (2i - 1) \right] \tan(\gamma) \quad (11)$$

$$\delta_{1,i}^c = -u_3 - \left[\frac{\Delta_c}{2} (2i - 1) + h_{cls,nc} \right] \tan(\theta_1) + \left[h_{cls} - \frac{\Delta_c}{2} (2i - 1) \right] \tan(\gamma) \quad (12)$$

$$\delta_3 = -u_1 - \left(h_{cs} + \frac{t_{bf}}{2} \right) \tan(\theta_1) \quad (13)$$

$$\delta_4 = -u_1 - \left(h_{cs} + h_b - \frac{t_{bf}}{2} \right) \tan(\theta_1) \quad (14)$$

$$\delta_{5,i} = u_4 - \left[h_{cs} - \frac{\Delta_{ct}}{2} (2i - 1) \right] \tan(\theta_2) - u_1 - \left[\frac{\Delta_{ct}}{2} (2i - 1) \right] \tan(\theta_1) \quad (15)$$

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling, Fig. 15 Component constitutive relationships: (a) concrete in compression,

(b) concrete in tension, (c) reinforcing steel, (d) shear stud, (e) panel zone in shear, and (f) lower T-stub in tension

Concrete slab in compression can be modeled using stress–strain relationships proposed in EC2 or any of the stress–strain relationships presented in sections “[Constitutive Law for Concrete Parts \(Based on the Kent–Park Model\)](#)” and “[Constitutive Law for Concrete \(Based on the Popovics–Saenz Law\)](#)” for both unconfined (concrete above reinforcement level) and confined (concrete below reinforcement level) conditions. A typical example of the stress–strain relationship that can be used in analysis is presented in Fig. 15a for both concrete

conditions. In tension (Fig. 15b), the behavior of concrete can be represented using a linear response until cracking, followed by a softening branch where the tensile resistance reduces exponentially as proposed by Stevens et al. (1991). Linear unloading–reloading branches can be adopted intersecting the deformation axis at a residual plastic deformation ϵ_{ct}^{PL} given by Eq. 22 and also shown in Fig. 15b:

$$\epsilon_{ct}^{PL} = 146 (\epsilon_{ct}^{max})^2 + 0.523 (\epsilon_{ct}^{max}) \quad (22)$$

Steel Reinforcement

Bilinear stress–strain relationships as shown on Fig. 15c can be adopted for representing the behavior of steel reinforcement.

Shear Connectors

The slip between the concrete slab and the beam owing to the flexibility of the shear stud connectors can be modeled using force–deformation relationships similar to those presented earlier in section “Interaction of Material Surfaces: Evaluation of Spring Properties” (“simulation of composite action”). The recommended force–deformation relationship for this particular model is based on the model proposed by Aribert and Lachal (2000) (and is tailored to the guidelines of EC4 and EC8 for the calculation of the ultimate shear stud resistance), and it is presented in Fig. 15d and Eq. 23.

$$F = Q_u \left(1 - e^{C_1(u_3 - u_4)} \right)^{C_2} \quad (23)$$

where

Q_u = ultimate shear stud resistance calculated according to EC4 and EC8

C_1, C_2 = coefficients suggested by Aribert and Al Bitar (1989) depending on the height of studs and type of steel profile

Panel Zone in Shear

The behavior of the panel zone plays a significant role in determining the overall stiffness and capacity of the frame. In terms of seismic design, the panel zone can have a significant influence on the distribution of plasticity and energy dissipation on the overall performance of the structure. A multi-linear shear force to shear deformation response is retained for the web panel zone. The following equations describe this multi-linear relationship through the gradients of elastic, post-elastic, and strain hardening stiffness:

$$K_{el, wp} = G_S \frac{A_{vc}}{z} \quad (23)$$

$$K_{t, wp} = 1.04 G_S \frac{b_{cf} t_{cf}^2}{z} \quad (24)$$

$$K_{s, wp} = \frac{G_S}{a_H} \frac{(h_c - t_{cf})t_{cw}}{z} \quad (25)$$

where

G_S = shear modulus of steel

A_{vc} = shear area of the column section

z = centerline vertical distance between the column stiffeners

b_{cf} = column flange width

t_{cf} = column flange thickness

h_c = column depth

t_{cw} = column web thickness

a_H = hardening coefficient related to the thickness of the column web panel and the column flanges

Using the elastic and post-elastic stiffness, shear forces in the panel zone can be obtained. The elastic stiffness, $K_{el, wp}$, is obtained from EC3 and is applicable until the shear force, V_{wp} , reaches the yield limit, $V_{el, w}$, which is also specified in EC3 (Eq. 26). The shear forces correspond to the post-elastic branches, described by Krawinkler’s model (Krawinkler 1978), in which the shear force is obtained through Eqs. 27 and 28. The three different branches of the shear force–deformation relationship are presented in Fig. 15e (dashed line):

$$V_{el, wp} = \frac{0.9 f_{y, cw} A_{vc}}{\sqrt{3}} \quad (26)$$

$$V_{t, wp} = \frac{0.9 f_{y, cw} A_{vc}}{\sqrt{3}} + 1.04 G_S \frac{b_{cf} t_{cf}^2}{z} 3 \gamma_y \quad (27)$$

$$V_{s, wp} = \frac{f_{u, cw} A_{vc}}{\sqrt{3}} + \frac{f_{u, cf} b_{cf} t_{cf}^2}{4z} \quad (28)$$

where

γ_y = panel distortion at yield = $V_{el, wp}/K_{el, wp}$

$f_{u, cw}, f_{u, cf}$ = ultimate tensile stress for column web and flanges

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling, Fig. 16 Cross-sectional model under negative bending

T-Stubs Components

The geometry of the equivalent T-stub components can be determined using the effective width concept presented in EC3 for stiffened columns and end-plates. The force–deformation relationship of T-stub elements required for component modeling can be obtained from the model proposed by Piluso et al. (2001) (dashed line) (Fig. 15f).

Simplifications and Assumptions

1. The difference in column web shear stiffness between the concrete-encased and non-encased segments of the columns should be taken into account in modeling through the assumption of infinite stiffness of the upper encased portion of the column and a flexible diagonal spring in the bare steel column web over the beam depth.
2. Bolt pretension effects need to be considered in modeling through modification of the stiffness of the equivalent T-stub springs in the elastic range.
3. There is an interaction between the connections on both column sides due to the continuity of the slab and the slab longitudinal steel reinforcement between the two beams. Hence, including the anchorage steel bars, the negative moment capacity of one side is dependent on the concrete capacity of the opposite side while essentially transferring the tensile forces acting from the reinforcing steel to the

column. The modeling engineer can use more advanced modeling procedures (i.e., as proposed by Fabbrocino et al. 2002) when continuous SCC beams are considered for the assessment of the behavior of the connection capacity, in terms of global quantities such as the rotations and deflections as well as local quantities such as the slip and the curvature of members, the interaction forces, and the rebar strain.

4. Column web buckling and beam flange buckling under compression are not considered in such modeling procedure.

Fabbrocino et al. 2002

1. Modeling the cross section of composite beams is achieved through a modification of the well-known Newmark's kinematic model, as shown in Fig. 16. This approach requires the definition of the slab effective width depending on the type of loading (hogging or sagging) and on the connection detailing at the beam end. A linear strain pattern is then applied to each component of the cross section. Under the assumption that the curvature and the rotation for each of the components are the same (e.g., for both the concrete slab and the steel profile), the uplift is neglected. Using analytical procedures, the tensile stresses developed in the concrete slab; the slip between the different components of the cross section; the interaction force, F ; the

global bending moments in the steel profile, M_s ; and the concrete slab, M_c , as well as the moment–curvature relationship of the cross section can be obtained.

2. Modeling the continuous composite beam is based on a combination of the main behavioral aspects on the different regions of the beam (i.e., Newmark's model is used for sagging moments, whereas its modified version is used when cracked zones of the beam are considered). The moment–curvature relationship in each section of the beam can be then defined through an iterative process. Once the generalized moment–curvature relationship is established, rotations and displacements can be obtained by integration of the curvature distribution. The numerical procedure for the solution of a simple structural system of a beam characterized by geometrical and mechanical symmetry is based on the compatibility method; therefore, the support bending moment is the main unknown and the beam is statically determined. The reader is referred to Fabbrocino et al. (2002) for a step-by-step guidance for the solution of the composite section and beam.

Modeling of the Panel Zone in Semirigid Steel–Concrete Composite (SCC) Connections

When moment-resisting frames are subjected to horizontal loading such as earthquake excitation, unbalanced moments occur at the beam-to-column connections resulting to shear deformations in the panel zones of the columns. Therefore, the behavior of the panel zone plays a significant role in determining the overall stiffness and capacity of the frame. In addition to this, in terms of seismic design, the panel zone can have a significant influence on the distribution of plasticity and energy dissipation mechanisms and in turn significant effects on the overall performance of the structure.

This section deals with the modeling of the panel zone region within the beam-to-column joints of SCC moment-resisting frames. This

particular model proposed by Castro et al. (2005) is based on a realistic stress distribution at the edges of the panel, aiming to account for the location of the neutral axis. This methodology enables assessment of the shear stress distribution through the panel depth representing the distribution of the plasticity in the vicinity of that region. Both shear and bending deformations are considered in the elastic and post-elastic stages. The additional resistance of the panel zone owing to the contribution of the column flanges is also taken into account by considering the column depth and flange thickness (Fig. 17).

Procedures and Details

With reference to Fig. 18, the physical dimensions of the panel zone, d_c and d_b , are taken into account. The part of the column being in contact with the slab is modeled through an assemblage of links on top of the panel. This modeling approach is essentially a determination of the spring properties of both the “panel zone” and the “top panel” which are derived analytically allowing for implementation in frame analysis software. The procedure establishes an analogy between the analytical (consisting of the actual connection) and the corresponding numerical model for frame analysis, as shown in Fig. 18.

The location of neutral axis is calculated considering a linear stress distribution, based on the assumption that the SCC beam behaves elastically until the panel yields.

An assessment of the effective width of the slab in the vicinity of the connection is also required. For positive moment (sagging), it is assumed that the slab is limited to the contact width of the column flange width, b_c . For negative moment (hogging), the slab is not considered, under the assumption that the reinforcement is not anchored to the column.

Notion of Calculations

The main aspect of the proposed model is the determination of the spring properties for both the panel zone and the top panel. For a given moment carried by the SCC beam, a corresponding equivalent shear is applied to the panel in the numerical model. The stiffness

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling, Fig. 17 Numerical and analytical representation of joint models

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling, Fig. 18 Analytical and numerical representation of joint models

that should be used in the numerical model can be then determined from the distortion caused to the analytical model owing to the application of moment. Furthermore, the difference between load level corresponding to first and full yielding of the panel can be derived given that the shear stress distribution through the panel is known. The procedure needed to be followed by the engineer for derivation of these important parameters

for both elastic and post-elastic ranges is outlined below.

This section serves as a numerical guideline; the reader is referred to J. M Castro et al. (2005) to exploit the complete set of equations.

Elastic Range

1. The neutral axis location of the steel beam and in turn its second moment of area can be

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling,

Fig. 19 The virtual system used to find panel deformations

calculated under the assumption that the steel beam behaves in an elastic manner up to yielding of the panel zone.

- The ratio of axial force (N_s) and bending moment (M_s) carried by the beam can be then obtained using analytical procedures.
- The total moment (M) acting to the connection can be then calculated in the numerical model using Eq. 29. The moment (M_c) developed in the slab is considered to have insignificant influence and therefore it is ignored:

$$M = M_s + N_s \left[\frac{d_b}{2} + d_s + \frac{t_{slab}}{2} \right] \quad (29)$$

- The equivalent moment carried by the panel can be then obtained from Eq. 30:

$$V_{eq} = \frac{M_s}{d_b} + \frac{N_s}{2} - V_{col} \quad (30)$$

where $V_{col} = \frac{M}{h_s}$ and h_s is the storey height.

- From the analytical model, knowing the normal stress distribution of the composite section, the shear force and bending moment distributions can be obtained.
- Using the principle of virtual work (Fig. 19) and the calculated shear force and bending moment distributions, the relative horizontal displacement can be obtained. Having the application of opposite unit forces in the virtual system, the internal virtual forces (V_{int} , M_{int}) can also be obtained.
- Using the calculated equivalent shear force (V_{eq}) and the relative horizontal displacements ($|\Delta_{shear}|$, $|\Delta_{bending}|$), the elastic stiffness

to be used in the numerical model is calculated by

$$K_{el} = \frac{V_{eq}}{|\Delta_{shear}| + |\Delta_{bending}|} \quad (31)$$

- Using the calculated elastic stiffness, the relative drift of the panel ($\Delta_{y,el}$) at the onset of yielding can be obtained analytically.
- Finally, using the calculated elastic stiffness and the relative drift of the panel zone, the elastic stiffness and the relative drift of the spring can be obtained using the Eqs. 32 and 33:

$$K_{el, spring} = \frac{K_{el}}{\cos^2 a} \quad (32)$$

$$\Delta_{el-y, spring} = \frac{\Delta_{y,el}}{\cos a} \quad (33)$$

where a is the angle of the spring as indicated in Fig. 18.

Post-Elastic Range

- Beyond the yielding of the panel, the shear stiffness of the column web is assumed to drop to the strain hardening stiffness of the material. Consequently, the post-elastic stiffness of the panel is provided by the strain hardening of the column web by the flanges and a portion of the column web delimiting the panel zone, as shown in Fig. 20. Following the same assumption for the beam remaining largely elastic, and by following similar procedures to those described for the elastic

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling, Fig. 20 The cross-sectional definition for the post-elastic range

range, the post-elastic stiffness for the panel can be obtained from Eq. 34:

$$K_{pl} = \left[\mu \frac{V_{eq}}{\Delta_{shear}} \right] + \left[\frac{V_{eq}}{\Delta_{bending}} \frac{2I_t}{I_{col}} \right] \quad (34)$$

where

μ = strain hardening parameter

I_t = second moment of area of the T-section obtained analytically

I_{col} = second moment of area of the column obtained analytically

2. The relative deformation, $\Delta_{y,pl}$, of the panel zone in the post-elastic range can be obtained using the principle of virtual work and can be readily derived as:

$$\Delta_{y,pl} = \Delta_{y,el} + \frac{\bar{f}_y d_b^2}{6E d_{CG}} \quad (35)$$

where

d_{CG} = distance from the centroid of the T-section to the external fiber of the column flange

$\bar{f}_y$ = reserve stress in the same fiber after shear yielding of the panel zone

3. Having known the calculated post-elastic stiffness and relative drift of the panel zone, the post-elastic stiffness and relative drift of the spring can be obtained using the Eqs. 36 and 37:

$$K_{pl, spring} = \frac{K_{pl}}{\cos^2 a} \quad (36)$$

$$\Delta_{pl-y, spring} = \frac{\Delta_{y, pl}}{\cos a} \quad (37)$$

4. Finally, the stiffness provided by the panel zone owing to strain hardening in shear (the first term of Eq. 34) is given by:

$$K_{S, Hardening} = \mu \frac{V_{eq}}{\Delta_{shear}} \quad (38)$$

Therefore, the strain hardening stiffness of the diagonal spring can be determined from

$$K_{S, H-Spring} = \frac{K_{S, Hardening}}{\cos^2 a} \quad (39)$$

Moment–Rotation Relationship of Panel Zone

The rotational springs in the panel zone are modeled using trilinear moment–rotation relationships while using the stiffness derived from the above expressions for the elastic and post-elastic range (later in Fig. 22). According to that figure, the panel zone is expected to behave in an asymmetric manner in tension and compression owing to the presence of concrete slab which influences the stiffness, yield moments, and cyclic behavior of the panel zone. Under negative moment, the concrete slab contribution is ignored owing to cracking of the concrete. Yield points (M_{py}^+ , θ_{py}^+) and (M_{py}^- , θ_{py}^-) are controlled by the steel yielding, and the ultimate points (M_{pu}^+ , θ_{pu}^+) and (M_{pu}^- , θ_{pu}^-) are controlled by the ultimate strength of the concrete. Under cycling loading, unloading occurs in a straight line with the same slope as the initial stiffness K_e . The reloading is directed towards the previous peak, thereby considering some strength and stiffness degradation.

Modeling of Frames Using Beam Elements

This section presents an analytical approach for the assessment of SCC frames under earthquake excitation using two-dimensional SCC beam

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling,

Fig. 21 Element relative forces and deformations in local coordinate system

elements (Kim and Engelhardt 2005). In order to model the behavior of SCC beams under earthquake excitation, factors such as the beam-to-column connection details, the local crushing of concrete, the loading pattern on beam, as well as the bond behavior between the reinforcing steel and the concrete need to be considered into the modeling. It is widely accepted that three-dimensional FE models can accurately predict the behavior of SCC beams at the expense of time and computational efficiency. On the other hand, these simpler but reasonably accurate two-dimensional SCC beam models can provide an alternative tool for frame response assessment.

Beam Elements

The beam elements are described as a one-component series hinge-type model combining analytical formulations calibrated against to experimental data and to other data from “sophisticated” described models, while intended to represent the clear span of beams in moment frames (i.e., the length of the beams between column flanges). The two-dimensional SCC beam elements are described by a linear elastic beam with a nonlinear zero-length hinge at each end; the resulting element is referred as “complete element.” Each of the hinges is described using nonlinear rigid-plastic moment–rotation relationships in order to simulate the real structural

behavior which was observed from experiments. Each complete element is characterized by two external and two internal nodes. The internal nodes are located between the connection of the linear elastic beam element and the hinges, while the external nodes connect the entire structure. Each of the external nodes has 3DOFs, 2-translations, and 1-rotation in the local coordinate system as presented in Fig. 21.

In the local coordinate system, the element can be considered as a simply supported beam given that the rigid body motions are removed. Based on equilibrium, using the values of relative forces (s_1 , s_2 , s_3), all the components of local nodal forces (R_1 to R_6) can be calculated. The transformation of forces is defined using the following relationship:

$$R = A s \quad (40)$$

where

A = force transformation matrix (this is well known and can be found in literature, i.e., Przemieniecki (1968))

From the geometry, the transformation from the local displacements, r , to the relative deformations (v_1 , v_2 , v_3) is performed by:

$$v = A^T r \quad (41)$$

where

$$\mathbf{r}^T = \{U_I, V_I, \theta_I, U_J, V_J, \theta_J\} \quad (42)$$

Element Stiffness

The initial stiffness of the aforementioned “complete element” is that of the linear elastic beam. As gradual yielding occurs at the hinges owing to increased moments at the element ends, the stiffness of the “complete element” reduces accordingly. In order to obtain the reduced stiffness at any load step after yielding, the instantaneous tangent flexibility of the nonlinear rigid-plastic force–deformation relationship for a hinge is combined with the flexibility of the elastic beam element.

A flexibility matrix, $\mathbf{f}$, is first formed for the elastic element including the effects of elastic shear deformation through the following relationship:

$$dq = \mathbf{f} ds \quad (43)$$

where

$dq = (dq_1, dq_2, dq_3) =$ elastic deformation increment at the internal nodes

$ds =$ action increment in which
 $ds^T = \{dF, dM^I, dM^J\} = \{ds_1, ds_2, ds_3\}$

For hinges at nodes I and J, the incremental action–deformation relationship is expressed by

$$dw_p = \begin{Bmatrix} 0 \\ d\theta_p^I \\ d\theta_p^J \end{Bmatrix} = \begin{Bmatrix} dv_1 - dq_1 \\ dv_2 - dq_2 \\ dv_3 - dq_3 \end{Bmatrix} = \mathbf{f}_p ds \quad (44)$$

where

$dw_p =$ vector of plastic hinge deformations at nodes I and J

$d\theta_p^I, d\theta_p^J =$ incremental plastic rotation at nodes I and J

$\mathbf{f}_p =$ hinge or plastic flexibility matrix in which nonzero terms are the second and third elements in the diagonal

Using Eqs. 43 and 44, the action–deformation relationship can be obtained for the “complete

element” expressed in terms of degrees of freedom, $\mathbf{v}$, as follows:

$$dv = ds + dw_p = \mathbf{F}_t ds \quad (45)$$

The hinge flexibility coefficients, $\mathbf{f}_p$, can be simply added to the appropriate coefficients of the elastic element flexibility matrix, $\mathbf{f}$, in order to obtain the tangent flexibility matrix, $\mathbf{F}_t$, for the “complete element,” as shown in Eq. 46. Once the 3×3 tangent flexibility matrix is obtained, it is then inverted to obtain the 3×3 tangent stiffness matrix, $\mathbf{K}_t$:

$$\mathbf{F}_t = \begin{vmatrix} \frac{L}{EA} & 0 & 0 \\ 0 & \frac{L}{EA^+} \mathbf{F}_{ii} + \frac{1}{GA_s L} + \mathbf{f}_p^i & -\frac{L}{EA^+} \mathbf{F}_{ij} + \frac{1}{GA_s L} \\ 0 & -\frac{L}{EA^+} \mathbf{F}_{ij} + \frac{1}{GA_s L} & \frac{L}{EA^+} \mathbf{F}_{jj} + \frac{1}{GA_s L} + \mathbf{f}_p^j \end{vmatrix} \quad (46)$$

where

$EA^+ =$ flexural rigidity of the composite beam

$EA =$ axial rigidity of the composite beam

$GA_s =$ effective shear rigidity of the composite beam

$\mathbf{F}_{ii} = \mathbf{F}_{ij} = 1/3$ and $\mathbf{F}_{jj} = 1/6$ for a uniform member

$\mathbf{f}_p^i, \mathbf{f}_p^j =$ flexibility of hinges at nodes I and J

Hysteretic Rules

Due to the cross-sectional asymmetry of the SCC beam, the response will be different for positive and negative moments. As a result, a hinge must discern the load paths to model the hysteretic behavior of SCC beam for an arbitrary cyclic loading. Apart of the cross-sectional asymmetry, the hysteretic rules employed for the complete element need to take into account factors such as the strength deterioration and the stiffness degradation.

In this part of the chapter, the hysteretic rules are determined from the modification of Lee’s model (1987) in order to better fit the curves and the nonlinear behavior of experimental test specimens. This model employs a specified

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling, Fig. 23 Plastic stress distribution for composite beam

The engineer is then required to calculate the effective width of the concrete slab on each side of the beam centerline for computing the positive elastic stiffness. This will enable the calculation of the second moment of inertia of the transformed SCC section. The effects of slip between the concrete and the steel on the positive elastic stiffness are taken into account through the use of a fraction of the second moment of inertia of the transformed SCC section. The calculation of the moment of inertia for the negative elastic stiffness needs to be performed, taking into account the steel beam section and the reinforcing steel bars within the effective slab width. The varying moment of inertia of SCC and cracked sections along the length of the beam is assumed to be equivalent to a uniform moment of inertia of a cracked section with reinforcing bars within the effective width.

Calculation of Moment at the Yielding and Ultimate Point Using a plastic stress distribution for SCC beams (Fig. 23), the ultimate moment (M_{max}) at the connection can be obtained. The positive yield moment (M_y^+) is assumed to be a fraction of the calculated ultimate moment. The negative yield moment (M_y^-)

is the plastic moment of both the steel beam section and the reinforcing steel bars within the effective width.

The contribution of the concrete slab to the ultimate moment at the connection is determined using the column width and a concrete compressive bearing stress of $1.3f'_c$, due to concrete confinement near the face of the column.

Modeling of SCC Frames with Concrete-Filled Steel Columns

The advantages of concrete-filled steel (CFS) structures in terms of high strength, high ductility, and large energy absorption led to their extensive use in high-rise structures in earthquake-prone regions.

This section presents a numerical procedure for the nonlinear inelastic analysis of CFS frames based on a fiber beam-to-column element. The nonlinear response of SCC frames is captured through the inelasticity of materials or due to changes in the frame geometry. Global geometric nonlinearities ($P-\delta$ effects) are taken into account by the use of stability functions derived from the exact stability solution of a beam-to-column element subjected to axial forces and bending

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling,
Fig. 24 Fiber hinge concept

moments. The spread of plasticity over the cross section and along the member length is captured by tracing the uniaxial stress–strain relationships of each fiber on the cross sections located at the selected integration points along the member length. The nonlinear equilibrium equations can be then solved using an incremental iterative scheme, based on the generalized displacement control method.

Fiber Beam-to-Column Element and Material Nonlinearity

The gradual plastification of a composite cross section can be described using the concept of fiber section model, similarly to the modeling of the concrete slabs in section “[Introduction](#).” The fiber model is presented in Fig. 24. The concept behind this model is rather simple; the cross-sectional area of the SCC element is subdivided into fibers represented by their area, A_i , and coordinate location (y_i , z_i – with origin the centroid of the section). Different material properties (e.g., concrete confined and unconfined, steel, reinforced steel) can be assigned to each of the fibers. Based on the relevant constitutive material

models, the fiber strains are used to calculate the fiber stresses, which are in turn integrated over the cross-sectional area to obtain stress resultants (i.e., forces and moments).

Using the fiber model, a number of assumptions have been made as follows:

1. Sections remain plane after bending.
2. Due to the latter assumption, cracking is considered to be smeared and normal to the member axis.
3. Torsional and shear effects are ignored.
4. Multi-axial stress states (due to the confinement effects) can be included in the model by increasing the concrete strength and modifying its post-peak response.
5. Local buckling effects or initial stress arising from thermal effects or erection loads are typically not included.

Confinement of Concrete-Encased Steel Sections

In order to utilize the material constitutive models described in the previous sections, the concrete confinement zones need to be identified (Fig. 25).

Seismic Analysis of Steel–Concrete Composite Buildings: Numerical Modeling,
Fig. 25 Confinement zones and distribution of monitoring points of SCC sections

Several methods for the identification of the confined zones have been suggested for partially and fully encased sections, and confinement factors, k , have been developed for use in numerical modeling. According to EC8, the confinement factor, k , is given by:

$$k = 1.0 + 5.0 \alpha_c f_l / f_{co} \quad \text{for } f_l / f_{co} < 0.05 \quad (47)$$

$$k = 1.125 + 2.5 \alpha_c f_l / f_{co} \quad \text{for } f_l / f_{co} \geq 0.05 \quad (48)$$

where

α_c = confinement effectiveness coefficient (area of concrete/area of confined concrete)

f_l = lateral confinement pressure from transverse reinforcement

f_{co} = unconfined concrete compressive strength

Local Flange Buckling

The flange buckling is a phenomenon that largely depends on the width-to-thickness ratio, the boundary (i.e., restraint) conditions, and the material properties of the components comprising the section. The effect of the local flange buckling is the reduction of the ultimate strength of the section and/or the diminishing of its rotational capacity in the inelastic range. Additionally, the ductility of encased SCC members is adversely affected by local buckling, and this needs to be considered when estimating the rotational capacity.

To account for the local buckling of bare and encased steel sections, simple methods have been developed and can be readily utilized in a frame analysis software. One of the most popular methods has been developed by Ballio et al. (1987). In this approach, the cross section is divided into a finite number, i , of strips with each strip having an assigned area. If the

compressive strain in any strip exceeds the critical strain, ϵ_{cr} , the area of the strip reduces to zero for the subsequent load cases. In order to extend the applicability of this method beyond the elastic limit into the inelastic range, the elastic critical stress is divided by the yield strain, as it is represented in the following relationship:

$$\frac{\epsilon_{cr}}{\epsilon_y} = \frac{k \pi^2 E}{12 \sigma_y (1 - \nu^2) \left(\frac{\lambda_i}{t}\right)^2} \quad (49)$$

where

λ_i = distance between the centroid of the strip and the plate connection

t = thickness of the plate

k = confinement factor

E = Modulus of elasticity of steel

ν = Poisson's ratio

Geometric Nonlinear P- δ Effect

Geometric nonlinearities can be classified in two categories. The first category is related to the global geometric nonlinearities, usually referred to as P- δ effects. The second category is related to local geometric nonlinearities (i.e., local buckling), which are generally neglected in frame analysis (while they are carefully considered in advanced finite element analyses with discretized models). The global geometric nonlinearities can be incorporated in the models following basic procedures used in nonlinear frame analysis. One of these procedures employs the updated Lagrangian formulation in order to account for geometric nonlinearities such as large displacements and rotations.

In most of the analyses of multi-storey structures subjected to earthquake excitation, the effects of the combination of gravitational forces and lateral displacement are ignored. Such effects are often referred as second-order effects. The reason behind overlooking the second-order effects can be explained by the fact that traditionally, in low-rising reinforced concrete structures

(i.e., structures with low natural period and small lateral displacement response) subjected to earthquake excitation, the second-order effects are insignificant and therefore neglected. As steel structures become taller nowadays, the P-Delta effects are amplified due to the corresponding increase of lateral displacement.

The effect of axial force acting through the relative transverse displacement of the member ends known as P- δ effect can be taken into account in the modeling by using the geometric stiffness matrix, $[K_g]$, as:

$$[K_g] = \begin{bmatrix} [K_s] & -[K_s]^T \\ -[K_s]^T & [K_s] \end{bmatrix} \quad (50)$$

where

$$[K_s] = \begin{bmatrix} 0 & \alpha & -b & 0 & 0 & 0 \\ \alpha & c & 0 & 0 & 0 & 0 \\ -b & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \quad (51)$$

and

$$\alpha = \frac{M_{zA} + M_{zB}}{L^2} \quad b = \frac{M_{yA} + M_{yB}}{L^2} \quad c = \frac{P}{L} \quad (52)$$

M_{zA} , M_{zB} , M_{yA} , M_{yB} = end moments with respect to z and y axes, respectively

P = axial force

L = length of the element

The tangent stiffness matrix of a beam-to-column element is then obtained by the following relationship:

$$[K]_{12 \times 12} = [T]_{6 \times 12}^T \times [K_e]_{6 \times 6} [T]_{6 \times 12} + [K_g]_{12 \times 12} \quad (53)$$

where

$$[T]_{6 \times 12} = \begin{bmatrix} -1 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -1/L & 0 & 1 & 0 & 0 & 0 & 1/L & 0 & 0 & 0 \\ -b & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1/L & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1/L & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1/L & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 \end{bmatrix} \quad (54)$$

and

$$\begin{aligned} [K_e]_{6 \times 6} &= \text{element stiffness matrix given by } \{\Delta F\} \\ &= [K_e] \{\Delta d\} \end{aligned}$$

The reader is referred to Thai and Kim (2011) for details on how to derive the element stiffness matrix.

Constitutive Models

Any of the constitutive models presented in the previous sections for steel, concrete, and steel reinforcement can be applied for modeling the material characteristics of the concrete-encased steel sections of the SCC frames.

Summary

The validity of the above case studies has been verified by comparing the numerical predictions with experimental data obtained from a wide range of structural systems subjected to static and hysteretic loadings. Full details of these comparative studies are presented in the literature. However, such constitutive laws and models are usually dependent on parameters which are evaluated through the particular use of the experimental data, and it is in the designers' discretion to choose and interpret these when data are used for specific purposes. In this chapter, it has been attempted to generalize the constitutive models for a number of applications. On the other hand, the lack of generality and objectivity that characterizes most FE packages can only be balanced through the use of material models which are compatible with valid experimental information. In fact, the work presented in

this chapter is considered as a step towards these directions.

The modeling of SCC members in this chapter (i) serves primarily the computation of the response of such members when they are subjected to seismic actions and (ii) acts as a vehicle for carrying out the state determination of the section (or integration point) to a frame element and ultimately to the whole frame assembly. The outcome of the former application is typically the moment–curvature response under a constant axial load. The latter application typically returns section forces that correspond to given section deformations (in uniaxial bending axial strain, and curvature).

In earthquake engineering, the stiffness of the column members is one of the most important parameters of the entire structural systems since it governs the lateral resistance of the frame. The natural period of vibration of the frame decreases with increasing stiffness but also increases with increasing mass. Therefore, the members comprising the frame need to be accurately simulated in order to derive the stiffness and mass matrices to be accounted for the frame analysis. According to the typical response spectra, the acceleration response of a SCC frame reduces with increased natural period. This implies that a composite structure will have to resist lower base shear; therefore, the earthquake effects will be less significant. The displacement response of the structure also increases proportionally with increasing natural period. For the case of increased lateral displacements, second-order effects ($P-\delta$ effects) could be developed which will determine the design and amplify the demand on the structure. The engineer is required to reduce the influence of the second-

order effects by controlling the lateral displacement of the frame providing ductility in the beams, columns, and connections. As a result, the accurate analysis of each individual component plays an important role in the aseismic design. In the holistic frame assembly, global geometric nonlinearities can be incorporated in the models following basic procedures used in the nonlinear frame analysis (i.e., modification of the stiffness matrix).

Using nonlinear static analysis, the engineer can obtain information on the global ductility and strength of the structure through force–displacement relations. At each point on the force–displacement curve, the engineer can check the member behavior and see whether the limit states are fulfilled. Weak areas and progressive hinge formation on the structural frame are revealed during the analysis.

Introduction

Wind power is one of the fastest-growing renewable energy segments on a percentage basis. In 2013, over 35 GW of new wind capacity was installed all over the world, bringing the total wind capacity to 318 GW at the end of 2013 (GWEC 2014). The total installed wind capacity is expected to reach 365 GW by the end of 2014,

Seismic Analysis of Wind Energy Converters, Fig. 1 Horizontal axis wind turbine (HAWT) in Egel, Germany (photo by Hadhuey)

enough to provide about 4 % of the global electricity demand (GWEC 2014).

While many different design solutions have been considered in the early stages, for commercial use the modern wind industry has now stabilized on horizontal axis wind turbines (HAWT). A typical example is shown in Fig. 1: a land-based tower with a nacelle mounted on the top, containing the generator, a gearbox, and the rotor. Typically, three-bladed upwind rotors are used.

With the continuous increase of wind power production, the search for optimal design is facing new and challenging tasks. The design of land-based HAWTs has been traditionally driven by high wind speed conditions. However, following the introduction of new technologies such as variable pitch and active control in larger, lighter, and cost-effective HAWTs, in some cases the design-driving considerations have been changed, with fatigue and turbulence being considered in addition to high wind speed conditions.

For these lighter HAWTs, especially when installed in seismically active areas, a question has soon arisen as to whether seismic loads shall be considered among design loads. On the other hand, the need to investigate the potential importance of seismic loads has been corroborated by the damage that occurred to land-based HAWTs, following the 1986 North Palm Springs Earthquake, USA, and the 2011 Kashima City Earthquake, Japan. Post-earthquake surveys in the wind farms nearest the epicenter of North Palm Springs Earthquake documented that 48 out of 65 HAWTs were damaged, generally due to buckling in the walls of the supporting tower (photographs are available in the report by Swan and Hadjian (1988)). Earthquake-induced failure may occur also at the foundation level, as for the case of the footing of a HAWT in the Kashima wind farm (photographs are available in the paper by Umar and Ishihara (2012)). In this context, the seismic assessment of HAWTs has drawn an increasing attention in the last years, and as a result, seismic loading has been progressively included in International Standards (ISs) and Certification Guidelines (CGs) (DNV/Risø 2002; GL 2010; IEC 2005; AWEA 2011).

The key points in the seismic assessment of HAWTs can be briefly summarized as:

- Selection of the load combinations
- Use of a specific analysis method
- Definition of the structural model

On these points, sufficient information is generally available in existing ISs and CGs. However, because a certain flexibility is allowed, especially in the definition of the structural model and the selection of an appropriate analysis method, it is important that engineers be aware of the potential options available and how they may affect the reliability of the results. In an attempt to respond to these needs, this entry will provide, first, a preliminary introduction to the relevant issues involved in the seismic assessment of HAWTs. Hence, detailed prescriptions of existing ISs and CGs will be reported and, finally, examples of the possible options for the implementation of the seismic assessment will be

presented. Throughout the entry, land-based HAWTs will be referred to.

Seismic Assessment of HAWTs

Load Combinations

The selection of appropriate load combinations for seismic assessment is a relevant issue addressed by ISs and CGs. In general, they are recommended based on the observations that follow.

At sites with a significant seismic hazard, there is a reasonable likelihood that an earthquake occurs while the HAWT is in an operational state, i.e., while the rotor is spinning; in this case, the HAWT is subjected to simultaneous earthquake loads and operational wind loads. It shall be considered, also, the possibility that the earthquake triggers a shutdown and that, as a result, the HAWT is subjected to simultaneous earthquake loads and emergency stop loads. Another possible scenario is that the earthquake strikes when the turbine is parked, i.e., not operating due to wind speeds exceeding the cutoff wind speed of the turbine; specifically, blades may be locked against motion (fixed pitch turbines) or feathered such that no sufficient torque is generated for the rotor to spin (active pitch turbines). In recognition of these observations, the load combinations generally suggested by ISs and CGs for the seismic assessment of HAWTs are:

- Earthquake loads and operational wind loads
- Earthquake loads and emergency stop loads
- Earthquake loads and wind loads in a parked state

Both earthquake loads and wind loads are stochastic processes. The wind process is generally treated as a stationary process. Samples can be generated from well-established power spectral densities (PSDs) in the literature (e.g., Von Karman PSD or Kaimal PSD, see Manwell et al. (2010)), with parameters to be set depending on site conditions. Wind acts on the blades of the rotor and along the tower.

Obviously, wind loading on the blades varies significantly depending on whether the rotor is spinning or not; to generate wind loading on a spinning rotor, concepts of classical aerodynamics are used, for instance, those of Blade Element Momentum (BEM) theory and subsequent modifications (Manwell et al. 2010). The earthquake process is inherently nonstationary. Spectrum-compatible samples may be synthesized from site-dependent response spectra or site-specific historical records may be used, according to the prescriptions of the adopted ISs and CGs.

Structural Analysis Method

The computation of the HAWT response to the different load combinations is a crucial step of the seismic assessment. In general, two approaches can be pursued:

- A fully coupled time-domain simulation computing the response to simultaneously acting wind loading and seismic loading
- A decoupled analysis where the responses to wind loading and seismic loading are computed separately and then superposed

A fully coupled time-domain simulation is the most desirable approach. The reason is that it allows the actual wind loads on the blades to be evaluated correctly, taking into account that the oscillations of the tower top, induced by the earthquake ground motion, affect the rotor aerodynamics (in particular, the relative wind speed at the blades, depending on which lift and drag forces are calculated). However, for the implementation of fully coupled time-domain simulations, dedicated software packages are required, capable of solving the nonlinear motion equations of the structural system under simultaneous wind and seismic excitations.

When performing a decoupled analysis, instead, the responses to wind loading and seismic loading are built separately. This means that wind loads are evaluated as no earthquake ground motion is acting at the tower base. Correspondingly, the response to the earthquake ground motion is computed as no wind loading is acting on the rotor. It is evident that this approach is

approximate since, as explained earlier, the actual wind loads on the blades depend on the oscillations of the tower top, to which contributes also the earthquake ground motion at the tower base. Nevertheless, numerical comparisons with benchmark results obtained by fully coupled time-domain simulations have shown that decoupled analyses can yield accurate results, provided that the separate response to earthquake loading is computed using an appropriate level of damping. In particular, it has been found that:

- A percentage equal to 5 % of critical damping is appropriate when the separate response to earthquake loading is to be combined with the response to operational wind loading, i.e., for the load combination = earthquake loads + operational wind loads (Witcher 2005; Prowell and Veers 2009; Prowell 2011).
- In contrast, a percentage varying between 0.5 % and 2 % of critical damping is appropriate when the separate response to earthquake loading is to be combined with the response to wind loading in a parked state, i.e., for the load combination = earthquake loads + wind loads in a parked state (Prowell and Veers 2009; Prowell 2011; Stamatopoulos 2013).

Such a variability of the damping level, to be considered in a decoupled analysis, can be explained as follows:

- The low damping ratios (0.5–2 %), which are required for the load combination = earthquake loads + wind loads in a parked state, are motivated by the fact that when the turbine is parked, the only damping source is the structural damping of the tower that, as customary in steel structures, is generally low.
- The higher damping ratio (5 %), which is required for the load combination = earthquake loads + operational wind loads, reflects the fact that the earthquake loading significantly affects the aerodynamics of a spinning rotor. In particular, a motion of the tower top due to the earthquake loading, against or in the wind direction, causes, respectively, an increase or a decrease of the instantaneous

thrust force, with respect to that computed assuming no earthquake ground motion at the tower base (such increase or decrease of the instantaneous thrust force mirrors an increased or decreased relative wind speed at the blades). Since, in both situations, this alternation of the thrust force is oriented opposite to the tower top motion, it can be understood that its effects are to be modeled by introducing additional damping with respect to the structural damping, when computing the separate response of the HAWT to earthquake loading. The same observation holds true when a decoupled analysis is performed to compute the response of HAWTs to combined wind loading and wave loading (Kuhn 2001).

The difference between damping for the parked state and operational state is generally referred to, in the literature, as *aerodynamic damping*, to mean that its source is essentially the rotor aerodynamics.

Decoupled analyses may be performed in time and frequency domain. Especially frequency-domain formulations have been awarded a considerable attention, because in this case the separate response to earthquake loading can be built by coded response spectra, a concept most engineers are familiar with. However, in light of the earlier observations on the appropriate level of damping, it is evident that particular care shall be taken when following this approach. In fact, the typical 5 % damped response spectra for building structures (ICC 2012) will be suitable only for the load combination = earthquake loads + operational wind loads, while 0.5–2 % damped response spectra shall be used for the load combination = earthquake loads + wind loads in a parked state. It is evident that selecting the correct damping ratio is crucial: if the response to earthquake loading was obtained from 5 % damped response spectra, nonconservative results would be certainly obtained when the turbine is parked. Some ISs and CGs take account of these issues (IEC 2005; AWEA 2011), but no explicit indications on the damping ratio to be adopted are given in the others (DNV/Risø 2002; GL 2010).

Structural Model

A fundamental assumption of existing ISs and CGs, with regard to the structural model, is material linearity. This assumption is essentially justified by the fact that the primary intent is to ensure power production for the design life of the HAWT, usually 20 years, and that nonlinear deformation (damage) to the turbine would interrupt reliable operation. Material linearity means low operational stresses, and this provides some safety margins against failure (Bazeos et al. 2002). Therefore material linearity will be, in general, a prerequisite of ISs and CGs also when assessing the response to seismic excitations.

Starting from the assumption of material linearity, in general, two types of structural modeling are feasible:

- Simplified models which model the tower and consider the rotor-nacelle assembly (RNA) as a lumped mass at the tower top
- Full system models which describe the whole turbine, including the nacelle and rotor with a certain level of detail

Simplified models are appealing since the complexities involved in modeling the rotor are avoided. Full system models include the rotor blades and, in general, turbine components such as power transmission inside the nacelle and pitch and speed control devices, with a different degree of accuracy depending on the specific modeling adopted, for instance, a finite element (FE) or a rigid multi-body modeling.

Simplified or full system models can be used depending on the selected structural analysis method. In particular:

- Fully coupled time-domain simulations involve only full system models as they require modeling the rotor aerodynamics, with the earthquake ground motion simultaneously acting at the tower base.
- Decoupled analyses may be implemented using either a full system model or a simplified model. If a simplified model is adopted, seismic loads are built considering the mass of

RNA lumped at the tower top, while wind loads are obtained by a dedicated software package, capable of modeling the rotor aerodynamics, with no earthquake ground motion at the tower base, since the analysis is decoupled.

International Standards and Certification Guidelines

Guidance for seismic loading on HAWTs can be found in the following ISs and CGs:

- DNV/Risø: Guidelines for design of wind turbines (DNV/Risø 2002). Released by Det Norske Veritas (DNV) and Risø National Laboratory
- GL 2010: Guideline for the certification of wind turbines (GL 2010). Released by Germanischer Lloyd (GL)
- IEC 61400-1: Wind turbine generator systems. Part 1: Safety requirements (IEC 2005). Released by International Electrotechnical Commission (IEC)
- ASCE/AWEA RP2011: Recommended practice for compliance of large land-based wind turbine support structures (ASCE/AWEA 2011). Released by American Society of Civil Engineers (ASCE) and American Wind Energy Association (AWEA)

DNV/Risø Guidelines

DNV/Risø Guidelines are meant to provide a basic introduction to the most relevant subjects in wind turbine engineering (DNV/Risø 2002). Consistently with this general purpose, quite general suggestions are given to deal with seismic loading.

It is prescribed that earthquake effects should be considered for HAWTs located in areas that are considered seismically active based on previous records of earthquake activity (Section 3.2.8). For those areas known to be seismically active but with no sufficient information available for a detailed characterization of seismicity, an evaluation of the regional and local geology is recommended to determine the

location of the HAWT relative to the alignment of faults, the epicentral and focal distances, the source mechanism for energy release, and the source-to-site attenuation characteristics. In this case, the evaluation should aim to estimate both the design earthquake and the maximum expectable earthquake, taking into account also the potential influence of local soil conditions on the ground motion.

No specific recommendations are given on the earthquake-wind load combinations to be considered. However, since it is prescribed that in seismically active areas the HAWT should be designed so as to withstand earthquake loads, it is implicit that the three, typical load combinations described earlier (i.e., earthquake loads and operational wind loads, earthquake loads and emergency stop loads, earthquake loads occurring in a parked state) shall be referred to.

As for what concerns the method of analysis, DNV/Risø provides explicit suggestions only for the response spectrum method, as used in a decoupled analysis. In particular, the use of a single degree-of-freedom (SDOF) system with a lumped mass on top of a vertical rod is suggested, with the rod length equal to the tower height and the lumped mass including the mass of the rotor-nacelle assembly (RNA) and $\frac{1}{4}$ of the mass of the tower. It is prescribed that the fundamental period of the SDOF system is used in conjunction with a design acceleration response spectrum to determine the loads set up by the ground motion, by analogy with the simplified procedures used in building codes. Analyses shall be performed for horizontal and vertical earthquake-induced accelerations. However, no explicit recommendations are given on the criterion to translate the resulting spectral response acceleration into design seismic loads, as well as on the damping ratio to be used. Since in the absence of specific guidance on this matter, a most intuitive choice of engineers could be using the typical procedures of the International Building Code (ICC 2012), it has to be remarked that the 5 % damping ratio, embedded in the standard design response spectrum, is appropriate only for seismic loading acting during an operational state, but overestimates considerably the

actual damping in a parked state. This aspect should be well kept in mind when referring to DNV/Risø for seismic assessment of HAWTs.

Regarding the structural model, attention is drawn to the need of including the actual stiffness of the structural component of the foundation and an appropriate model of the supporting or surrounding soil, the latter through a proper soil structure interaction (SSI) modeling (Section 8.4). Although, for this purpose, nonlinear and frequency-dependent models are recommended in principle, appropriate linearized models are allowed, depending on the expected strain level in the soil (typically, it may be up to 10^{-1} for earthquake loading and considerably larger than for other loading conditions). The linearized models consist of translational and rotational springs for circular footings and piles.

GL Guidelines

GL 2010 guidelines aim to set a number of requirements for the certification of wind turbines (GL 2010). For this reason, they are quite prescriptive and provide detailed information on some particular aspects of seismic risk.

In agreement with DNV/Risø, GL 2010 prescribes that seismic loading shall be taken into account in seismically active areas (Section 4.2.4.2.3). Earthquake loading is included in a group of design load cases (Table 4.3.2) classified as load cases accounting for “extended” design situations, including special applications and site conditions. These design load cases are not mandatory for certification purposes, but may be chosen for the verification of the HAWT to complement the applicability in specific design situations. The response to seismic loading is to be assessed both in the operational state and the parked state (Table 4.3.2) under normal wind loading. For the operational state it is also suggested to consider the activation of the emergency shutdown triggered by the earthquake. The safety factor for all the loads to be combined with seismic loading is equal to 1.0 (Section 4.3.5.4). A return period of 475 years is prescribed as the earthquake design level. To model the seismic loading, recommendations of the local building

code should be applied or, in the absence of locally applicable regulations, those of either Eurocode 8 (2004) or American Petroleum Institute (API 2000).

Regarding the method of analysis, GL 2010 specifies that fully coupled or decoupled analyses are possible, with at least three modes in both cases. Time-domain simulations shall be carried out considering at least six simulations per load case. As with DNV/Risø, no guidance is provided on the damping ratio to be adopted when using the design response spectrum in a decoupled analysis. Again, because of the lack of guidance on this matter, it shall be kept in mind that the 5 % damping ratio is appropriate only in the operational state and that lower damping ratios shall be considered in the parked state.

GL 2010 gives no particular prescriptions on the structural model to be adopted. However, because at least three modes have to be included in the vibration response, the use of a multi-degree-of-freedom (MDOF) structural model is implicitly suggested. In general, a linear elastic behavior shall be assumed. A ductile response can be considered only when the support structure has a sufficient static redundancy, such as a lattice tower. However, if ductile behavior is assumed, the structure shall be mandatorily inspected after occurrence of an earthquake.

IEC Standards

IEC 61400-1 Standards aim to specify essential design requirements to ensure structural integrity of wind turbines (IEC 2005). They have the status of national standards in all European countries whose national electrotechnical committees are CENELEC members (CENELEC = European Committee for Electrotechnical Standardization).

IEC 61400-1 recommends that, in seismically active areas, the integrity of the HAWT is demonstrated for the specific site conditions (Section 11.6), while no seismic assessment is required for sites already excluded by the local building code, due to weak seismic actions. The seismic loading shall be combined with other significant, frequently occurring operational

loads. In particular, IEC 61400-1 prescribes that the seismic loading shall be superposed with operational loads, to be selected as the higher of:

- (a) Loads during normal power production, by averaging over the lifetime
- (b) Loads during emergency shutdown, for a wind speed selected so that the loads prior to the shutdown are equal to those obtained with (a)

No explicit reference is made, however, to the loaded case of an earthquake loading striking in a parked state.

The safety factor for all load components to be combined with seismic loading shall be set equal to 1.0. The ground acceleration shall be evaluated for a 475-year recurrence period based on ground acceleration and response spectrum requirements as defined in local building codes. If a local building code is not available or does not provide ground acceleration and response spectrum, an appropriate evaluation of these parameters shall be carried out.

Regarding the method of analysis, fully coupled or decoupled analyses are possible (11.6). In time-domain analyses, sufficient simulations shall be undertaken to ensure that the operational load is statistically representative. It is prescribed that the number of tower modes used in either of the above methods shall be selected in accordance with a recognized building code. In the absence of a locally applicable building code, consecutive modes with a total modal mass of 85 % of the total mass shall be used.

IEC 61400-1 gives no particular indications on the structural model for seismic analysis. In agreement with GL 2010, however, it is implicit that the structure shall be modeled as a MDOF system, since the use of consecutive modes with a total modal mass equal to at least 85 % of the total mass is recommended. In general, the response should be linearly elastic, while a ductile response with energy dissipation is allowed only for specific structures, in particular for lattice structures with bolted joints.

Annex C of IEC 61400-1 presents a simplified, conservative method for the calculation of seismic loads. This procedure is meant to be used when the most significant seismic loads can reasonably be predicted on the tower, and shall not be used if it is likely that the earthquake ground motion may cause significant loading on the rotor blades or the structural components of the foundation. The principal simplifications in Annex C are ignoring the modes higher than the first tower bending mode and the assumption that the whole structure is subjected to the same acceleration. Upon evaluating or estimating the site and soil conditions required by the local building code, or adopting conservative assumptions while detailed site data are not available, the simplified method can be applied as follows:

- The acceleration at the first tower bending natural frequency is set using a normalized design response spectrum and a seismic hazard-zoning factor. For this, a 1 % damping ratio is assumed.
- Earthquake-induced shear and bending moments at the tower base are calculated by applying, at the tower top, a force equal to the total mass of the RNA + $\frac{1}{2}$ the mass of the tower times the design acceleration response.
- The corresponding base shear and bending moments are added to the characteristic loads calculated for an emergency stop at rated wind speed, i.e., the speed at which the limit of the generator output is reached.
- The results are compared with those obtained against the design loads or the design resistance for the HAWT. If the tower can sustain the resulting combined loading, no further investigation is needed. Otherwise, a thorough investigation shall be carried out on a MDOF structural model.

With regard to such a simplified method, described in Annex C, it shall be pointed out that ignoring the second tower mode is a significant nonconservative simplification (e.g., see Zhao and Maisser (2006) on the role of the second tower mode in the seismic response of HAWTs).

This is somehow compensated for by incorporating $\frac{1}{2}$ of the tower mass with the tower head mass and prescribing superposition with the characteristic loads calculated for an emergency stop at rated wind speed, which represent quite conservative aerodynamic loads.

ASCE/AWEA Recommended Practice

The general purpose of ASCE/AWEA RP2011 is to clearly identify specific US national recommendations for wind turbine design, which are compatible with IEC 61400-1 but may provide proper recommendations for those cases in which US practice and IEC 61400-1 differ. As for what concerns seismic assessment, ASCE/AWEA RP2011 makes a quite comprehensive effort to harmonize some relevant specific prescriptions of certification agencies with the traditional perspectives of US standards ASCE/SEI 7-05, which sets the minimum design loads for buildings and structures in general (ASCE 2006). For the level of detailed information provided, ASCE/AWEA RP2011 can be considered a very useful and comprehensive reference tool for the seismic assessment of HAWTs.

ASCE/AWEA RP2011 points out that although standard HAWT classes shall be generally designed for normal wind conditions, extreme wind, conditions and other environmental conditions including temperature and air density, specific prescriptions on the criteria for the design of HAWTs subjected to earthquake ground motions are necessary, in recognition of the fact that earthquake events are common in many US jurisdictions. According to ASCE/AWEA RP2011, it is of critical importance to recognize that seismic loads plus operational loads may in some cases govern tower and foundation design. For these reasons, load combinations involving earthquake occurring in an operational state and earthquake triggering emergency stop loads, an earthquake occurring in a parked state should be considered (Section 5.4.4). Seismic ground motion values should be determined based on the acceleration response spectrum or site-specific ground motion procedures as prescribed by ASCE/SEI 7-05 (see Section 11.4 and Chapter 21 in ASCE/SEI 7-05).

Unlike the alternative ISs and CGs, ASCE/AWEA RP2011 provides quite detailed prescriptions on a “best practice” load combination including seismic loads plus operational loads:

$$U = (1.2 + 0.2S_{DS})D + 0.75(\rho Q_E + 1.0M) \quad (1)$$

$$U = (0.9 - 0.2S_{DS})D + 0.75(\rho Q_E + 1.0M) \quad (2)$$

where:

U = factored load effect

D = dead load

M = operational loading equal to the greater of (1) loads during normal power production at the rated wind speed or (2) characteristic loads calculated for an emergency stop at rated wind speed

Q_E = effect of horizontal seismic (earthquake-induced) forces

S_{DS} = design spectral response acceleration parameter at short periods

$\rho = 1.0$, redundancy factor (for nonbuilding structures not similar to buildings $\rho = 1.0$, according to Chapter 12.3.4.1 of ASCE/SEI 7-05)

ASCE/AWEA RP2011 suggests Equations 15.4-1 and 15.4-2 of ASCE/SEI 7-05 for the seismic response coefficient C_s (nonbuilding structures), if Equation 12.8-1 of ASCE/SEI 7-05 is used to compute the seismic base shear. Specifically, in Eq. 15.4-2 of ASCE/SEI 7-05 for C_s a response modification factor $R = 1.5$ is recommended by ASCE/AWEA RP2011. The use of $R = 1.5$ does not necessarily imply that a ductile response or material overstrength is expected but accounts for a certain conservatism in the seismic response coefficient C_s prescribed for nonbuilding structures.

In Eqs. 1 and 2, the use of a load factor of 0.75 on both seismic loads and operational loads is supported by results of time-domain analyses on HAWTs ranging from 65 to 5 MW, subjected to 100 earthquake ground motion records, for varying orientation of wind and earthquake loads (Prowell 2011). It is observed that when the seismic hazard at a particular site is dominated by

known faults, consideration of site-specific prevailing wind direction and maximum earthquake component direction may be appropriate. In this case no load factor may be applicable, if wind and wave propagation directions are expected to coincide.

ASCE/AWEA RP2011 recommends that for load combinations not including operational loads, the spectral response acceleration parameter should be based on a 1 % damping ratio, which reflects the low inherent damping of typical steel support structures for HAWTs. The multiplicative spectral adjustment factor, B , to adjust spectral response acceleration, S_a , from 5 % (standard IBC value for determining S_a) to 1 % damped values is equal to 1.40 (Table 5-6). For load combinations that include operational loads, the spectral response acceleration parameter should be based on 5 % damped values. ASCE/AWEA RP2011 points out that this increase in damping is based on the aerodynamic damping inherent to an operating HAWT as verified by experimental and numerical results showing that a damping level of 1 % produces overly conservative results (Prowell 2011).

Regarding the method of analysis, according to ASCE/AWEA RP2011 a fully coupled time-domain analysis and decoupled analyses based on equivalent lateral force method or modal response spectrum method are acceptable, as permitted by the local building code. For the specific implementation of each method of analysis, the local building code or ASCE/SEI 7-05 is referred to. In particular, if the equivalent lateral force procedure is used, the vertical distribution of seismic forces should be calculated based on the procedure given in ASCE/SEI 7-05, Chapter 12.8.3, with some modifications: the seismic forces corresponding to the seismic weight of the RNA should be located at the turbine's center of gravity, and those corresponding to the seismic weight of the tower structure (including ladders, platforms, railings, etc.) should be distributed to nodes distributed along the tower height. No further prescriptions are given on a specific structural model to be adopted, when implementing a fully coupled or a decoupled analysis.

As for what concerns decoupled analyses, ASCE/AWEA RP2011 suggests that in those cases when only the peak seismic loads and peak operational loads are available, the proposed combination method for seismic loads and operational loads may be overly conservative, especially in recognition of the fact that the respective peak loads do not occur at the same instant of time and in the same loading direction. Therefore, to reduce potential design conservatism and obtain a more accurate prediction of the response, fully coupled time-domain analyses are suggested, considering earthquake ground acceleration in combination with operational or emergency stop loads. Seismic analysis should comply with the requirements of ASCE/SEI 7-05, Chapter 16, concerning, for instance, the minimum number of simulated earthquake ground motions. It is recommended that time-domain analyses be conducted with analysis software capable of simulating the structural response and global turbine dynamics, including the aerodynamic interaction.

ASCE/AWEA RP2011 gives some interesting points of view on the applicability of typical prescriptions of building codes to HAWTs design. For instance, according to ASCE/AWEA RP2011, enhanced performance objectives may be established to meet specific owner requirements and to improve expected behavior during and after an earthquake. For this purpose the use of a performance factor, similar to an importance factor of 1.5 for essential facilities, is suggested. This performance factor shall be agreed with the wind turbine manufacturer to establish acceleration thresholds for turbine components that will ensure operational performance. Also, according to ASCE/AWEA RP2011, no specific drifts or displacement need to be defined. This is motivated essentially by the fact that thorough analysis and design considerations of the ultimate and fatigue limit states implicitly limit the displacements of the tower. In addition, the wind turbine controls monitor and limit the possible tower top accelerations, to prevent exceeding the design loading.

Another distinctive feature of the ASCE/AWEA RP2011 is the emphasis put on

consideration of seismic forces in the foundation design, for areas with historical earthquake activity. Evaluation of earthquake effects should be performed in accordance with the requirements of the local building code or IEC 61400-1. In any case, geotechnical evaluation of earthquake effects should include ground shaking, liquefaction, slope instability, surface fault rupture, seismically induced settlement/cyclic densification, lateral spreading, cyclic mobility, and soil strength loss. In areas susceptible to earthquake effects, appropriate mitigation should be provided for foundations. For projects located near active faults, the characteristics of the fault including type, seismic setting, subsurface conditions, ground motion attenuation, and maximum earthquake magnitude should be considered. At any rate, HAWTs should be located with adequate setbacks from fault zones. Where relatively loose unsaturated cohesionless soils are present at the project site, the effect of ground shaking from a design level earthquake should be taken into account. Also, potential settlement due to cyclic densification of the site soils should be evaluated.

Implementation of Seismic Assessment

Despite the prescriptions given by existing ISs and CGs (DNV/Risø 2002; GL 2010; IEC 2005; ASCE/AWEA 2011), engineers dealing with the seismic assessment of HAWTs may face a few issues, which are only partially addressed by ISs and CGs. This section is meant to provide some insights into these aspects, illustrating the most relevant studies for this purpose. Although investigations are not fully accomplished, it is worth mentioning these studies, as they may provide engineers with very useful data for a correct seismic assessment of HAWTs.

As mentioned earlier, an important step is the construction of the structural model. Simplified models, which avoid the complexities involved in modeling the rotor, are frequently used, especially for a preliminary design. In contrast, for a comprehensive investigation of all factors relevant to seismic risk, full system models are generally considered. They allow prediction of

component loads instead of only tower loads, which cannot be estimated in a simple tower-based model. In this regard, it is remarked that higher modes involving the rotor dynamics may play an important role, as they may fall in the region of maximum spectral response acceleration (Prowell et al. 2010).

Regardless of the structural model adopted, another important issue in the seismic assessment of HAWTs is SSI modeling. Modeling the base as fixed, with no consideration of the SSI, could be justified in the case of overdesigned foundations and stiff soil conditions. However, HAWTs may be installed on relatively soft soils or loose soils containing alluvial deposits, and under these circumstances the SSI modeling, particularly for dynamic loads, could become a major concern in the design of the foundation and, consequently, of the entire support structure of the HAWT (Bazeos et al. 2002; Zhao and Maisser 2006). A proper SSI modeling may play an important role also in consideration of the ground motion amplification effects on soft and loose soils.

In the following, simple and full system models will be described briefly as used in the recent literature, along with relevant information on SSI modeling.

Simple Models

One of the first studies on the seismic response of HAWTs has been carried out by Bazeos and coworkers (Bazeos et al. 2002). They have investigated a 38 m high HAWT resting on a concrete block, located in a site with 0.12 g peak ground acceleration and semi-rock soil conditions. Seismic analyses have been conducted on two different models, a FE model of the tower with shell elements and a simplified FE model with lumped masses along the tower height and 3D beam elements approximately mapping mechanical and geometrical properties of the tower. In both models, a top mass has been added to model the RNA; SSI has been modeled by a set of discrete springs and dashpots and, adding to the mass of the concrete foundation block (modeled as rigid), a virtual soil mass moving in phase (Mulliken and Karabalis 1998). Parked conditions only have been considered, with no aerodynamic loads

along the tower. Seismic analysis has been carried out in the time domain using ground motions compatible with the elastic response spectrum, as prescribed by the Greek Aseismic Code with 0.5 % damping. For the relatively low ground acceleration under consideration (0.12 g), low stress levels have been found due to seismic excitations, with respect to the stress levels due to wind in either operational or emergency states. Results obtained by the time-domain simulations on the two FE models have been validated by a response spectrum analysis on a SDOF system with a mass set equal to the total mass of the system and a stiffness computed from the first natural period of the FE model with shell elements. Interestingly, Bazeos and coworkers (2002) have showed that higher tower modes can be significantly affected by SSI modeling. This result is important in consideration of the fact that the natural frequencies of the higher tower modes may fall within the region of maximum spectral acceleration (Haenler et al. 2006).

Umar and Ishihara (2012) have focused on the construction of a response spectrum for HAWTs under seismic excitations only, i.e., in a parked state. The need for a specific response spectrum is motivated by the observation that the support structures for HAWTs exhibit, unlike buildings, long period, heavy top, and different mass distribution along the height. Besides this general observation, by carrying out numerical simulations using a database of strong earthquake ground motions, they have shown that the very low damping levels in parked conditions determine excessive fluctuations in the response spectrum, and such uncertainty cannot be captured by existing damping correction factors in Eurocode 8 (2004) and Japanese Building Standard Law (BSL 2004). Umar and Ishihara (2012) have modeled the HAWT as a MDOF system with a lumped mass at the top, and a sway-rocking model to take into account SSI effects. They have proposed a modified correction factor for the damping ratio of the BSL response spectrum used in Japan (BSL 2004), depending on the natural period and the targeted reliability. They have shown that the maximum seismic loads, as obtained by a complete quadratic combination of

five modal responses obtained by the specified design spectrum, match very well the corresponding values obtained with time series analyses. Results have been provided for HAWTs with different size.

Stamatopoulos (2013) has addressed the response of HAWTs to near-fault ground motions. He has investigated a 53.95 m tall turbine resting on a circular footing. A FE model of the tower and the circular footing has been used, with a lumped mass at the tower top modeling the RNA; SSI has been modeled by uncoupled nonlinear springs distributed below the footing. The response to near-fault ground motion has been investigated by three methods: a response spectrum method based on the elastic acceleration spectrum provided by the Greek Aseismic Code, suitably increased by 25 % to account for proximity to a seismic fault; a response spectrum method involving an elastic local acceleration spectrum built based on actual records for the project site; and a time history analysis using synthesized ground motions compatible with the elastic local acceleration spectrum. The two response spectrum analyses have been carried out on a FE model with the tower grounded by a linearly elastic rotational spring, with stiffness computed as the ratio of the bottom bending moment to the bottom rotation. An iterative procedure has been implemented, since the bottom bending moment and rotation depend on the seismic loading computed from the spectral acceleration; the latter depends on the first natural period, which depends in turn on the stiffness of the grounded rotational spring. Stamatopoulos (2013) has shown that the acceleration spectrum provided by the Greek Aseismic Code, although appropriately increased to account for proximity of seismic fault, significantly underestimates the shear and bending moment demand at the tower base by 55 %.

Nuta and coworkers (2011) have proposed a methodology to assess the probability of failure of a HAWT under seismic excitations in a parked state. Despite material linearity is generally prescribed for design, in fact, nonlinear behavior has to be taken into account when examining the potential failure mechanisms induced by seismic

excitations. For a HAWT with 1.65 MW rated power and 80 m hub height, they have built log-normally distributed fragility curves to estimate the probability of reaching a defined damage state. Parameters of the lognormal distributions have been obtained from nonlinear incremental dynamic analyses, assuming the magnification factor with respect to the design earthquake as intensity measure, and peak displacement, peak rotation, residual displacement, and peak stress as damage measures. For the specific sites of this study, two in Canada and one in the USA, no significant probability of failure has been found for the 1.65 MW HAWT under consideration (Nuta et al. 2011).

Full Models

In the last few years, a significant effort has been spent on developing advanced tools that may allow a full system modeling of HAWTs. Due to computational complexity involved in a FE modeling of all components of a HAWT, models with a limited number of degrees of freedom have been built, and, in general, a modal approach, a multi-body approach, or a combination of the two has been used. Many high quality full-modeling software packages are now available for the wind industry, such as GH BLADED (Bossanyi 2000) and FAST (Jonkman and Buhl 2005), developed at the United States National Renewable Energy Laboratory (NREL). A few comments on these packages are in order, especially with regard to the options available for seismic analysis.

GH BLADED uses a multi-body dynamics approach in conjunction with a modal representation of the flexible components like tower and blades (Bossanyi 2000). A fully coupled time-domain simulation is feasible, with wind and seismic loadings simultaneously generated. Two methods are available for simulating seismic loading. The first method allows recorded acceleration time histories to be used, while the second method uses an iterative procedure to synthesize acceleration time histories providing an elastic response spectrum that closely matches a specified design response spectrum. SSI can be also modeled. GH BLADED has been validated by GL for calculating operational loads associated

with typical load cases. A combined multi-body dynamics and modal formulation is adopted also by FAST (Jonkman and Buhl 2005), with flexible components modeled based on user-provided mode shapes. A fully coupled time-domain simulation can be implemented, with seismic loading generated as a user-defined loading imposed at the tower base. Like GH BLADED, FAST has been validated by GL.

Using BLADED, Witcher (2005) has compared the results from a response spectrum method and time-domain simulations as applied to a 60 m tall 2 MW turbine subjected to earthquake ground motion in both operational and parked cases. He has found that the elastic design spectrum with 5 % damping ratio yields a maximum bending moment at the tower base in a very good agreement with that computed by time-domain simulations, thus inferring that aerodynamic damping experienced by an operating turbine is quite close to 5 %. However, the results of the response spectrum method and time-domain analyses were very different in the parked case, with the first significantly underestimating the maximum tower base bending moment. This result has confirmed that in the parked case no aerodynamic damping is generated and that using the response spectrum method with a 5 % damping ratio does lead to nonconservative results. Although, in the specific case under examination, the bending moment demand due to earthquake loading in the parked case was lower than that due to earthquake loading in the operational case, Witcher (2005) has drawn the attention to the fact that, in some cases, the driving load can be that corresponding to earthquake loading in the parked case and has recommended further investigations on this issue.

Using FAST, one of the most comprehensive and fruitful studies on the seismic assessment of HAWTs has been carried out by Prowell and coworkers (2013). They have run a multiyear research program including extensive numerical simulations with FAST on HAWTs featuring different sizes and rated power (65 kW; 900 kW; 1.5 MW and 5 MW) and experimental tests on a HAWT (65 kW rated power, 22.6 m hub height, and a 16 m rotor diameter) mounted on the

Seismic Analysis of Wind Energy Converters,

Fig. 2 HAWT on the outdoor shake table at the University of San Diego, CA. The *arrows* indicate the direction of shaking (From Prowell et al. 2013)

outdoor shake table at the University of California, San Diego (Fig. 2). Prowell and coworkers have collected a considerable amount of data, which has also served as a basis for ASCE/AWEA RP2011 prescriptions. Using a set of 99 ground motions with different magnitude and source-to-recording distance, they have run numerical simulations showing that the considered earthquakes may produce, in the 5 MW HAWT, a bending moment demand at the tower base well above that from extreme wind events. This result has been found for parked, operational, and emergency shutdown simulations and confirmed that seismic loads may be design driving for large turbines in regions of high seismic hazard.

As for what concerns the experimental tests on the 65 kW HAWT, only a few key results are reported here, but interested readers can find detailed information on both numerical and experimental findings in the study by Prowell and Veers (2009), Prowell et al. (2010, 2013), Prowell (2011), and references therein. Experimental tests were carried out in operational and parked states. In each state, shaking has been imparted in two directions, one parallel (FA =

fore-aft) and another perpendicular (SS = side-to-side) to the rotation axis of the rotor. Structural response characteristics have been recorded for motions imparted in both configurations and both operational states (Prowell et al. 2013).

The results have shown that for shaking imparted in the SS direction, no appreciable differences are encountered between operational and parked states, in terms of bending moment envelopes (Fig. 3b). In contrast, for shaking imparted in the FA direction, the bending moment demand at the tower base in the operational state was reduced by approximately 15–33 % from that while parked (Fig. 3a). This reduction of demand confirmed that in the operational state, aerodynamic damping has to be accounted for when performing a decoupled analysis, with separately generated wind loading and seismic loading (Prowell et al. 2013). However, due to the influence of many factors such as wind speed, earthquake magnitude, wind and earthquake relative directions, and SSI modeling, multiple simulations including likely distributions of wind speed and earthquake shaking have been recommended for an accurate quantification of the aerodynamic damping (Prowell et al. 2013).

Seismic Analysis of Wind Energy Converters,

Fig. 3 Experimental bending moment envelope for three earthquake ground motions (From Prowell et al. 2013)

Seismic Analysis of Wind Energy Converters,

Fig. 4 Experimental acceleration envelope for three earthquake ground motions (From Prowell et al. 2013)

The same simulations should serve for a probabilistic description of the influence of seismic excitations on extreme loads.

A further important result obtained by Prowell and coworkers (2013) concerns the relative contributions of various tower modes. The maximum

absolute acceleration envelopes in the FA and SS direction have shown that, in addition to the first mode, the second mode contributes significantly, as indicated by the high acceleration values at two thirds of the tower height (Fig. 4). This result has confirmed what predicted by other

Seismic Analysis of Wind Energy Converters,

Fig. 5 SSI modeling for seismic assessment of HAWTs (From Zhao and Maisser 2006)

researchers (Haenler et al. 2006) on the importance of the second tower mode for estimation of seismic loads on large turbines. However, on the basis of the response PSDs, it has been found that amplification of energy imparted near the frequency of the second modes was not significantly influenced by operational state, thus implying that aerodynamic damping shall preferably be accounted for only in the first mode response (Prowell et al. 2013).

Besides the software packages used by the wind industry, there exist also a few full models of HAWTs, which have not been translated in software packages for the wind industry yet, but have provided very interesting results on the seismic response of HAWTs.

For instance, Zhao and coworkers (Zhao and Maisser 2006; Zhao et al. 2007) have developed a hybrid multi-body system (MBS) for full modeling of HAWTs. By this approach, the elastic tower is discretized into a series of rigid bodies coupled elastically by constraint joints and springs. The wind rotor is treated as a rigid disk; nacelle and machine carrier are coupled by an in-plane joint and treated as a rigid ensemble connected to the tower top through a revolute joint. The governing equations are derived using Lagrange's equations. This approach, though more mathematically rigorous, does not require external calculation of component mode shapes.

The MBS has been used by Zhao and Maisser (2006) to assess the seismic response of a 65 m high HAWT. SSI has been modeled approximately by a frequency-independent discrete parameter model, as a 3D set of uncoupled spring-damper devices, including translations and rotations (Fig. 5).

Seismic analysis has been carried out in operational conditions with a three-component weak real earthquake record. Numerical results have showed that while the top displacement is dominated by the wind thrust, force and bending moment in the longitudinal direction at the tower base are affected considerably by earthquake loads. In addition, in the lateral direction (where there are no wind loads), the force and bending moment are essentially decided by the earthquake loads and amplify several times.

Another interesting result concerns the lateral reaction force at the main bearing that is found to be significantly increased with respect to the case of no earthquake loading. This increase of the lateral reaction force is attributed to the gyroscopic forces that arise because of the change of the wind rotor direction, due to the earthquake loading. A further result of the study by Zhao and Maisser (2006) is that SSI modeling affects significantly the higher tower modes, especially the second lateral bending mode. In this respect, this result confirms the results obtained by Bazeos

et al. (2002) using a simplified model of the HAWT and shall be taken into account in consideration of the fact that especially the higher tower modes may fall within the region of maximum spectral acceleration (Haenler et al. 2006).

Using a multi-body system with flexible parts (tower, blades) described by a variable number of modes and including SSI modeling, Haenler and coworkers (2006) have investigated the seismic response of a HAWT with an 80 m rotor diameter and 60 m hub height, operating under a 13 m/s wind speed and subjected to an earthquake ground motion with a 0.3 g peak ground acceleration (PGA). They have showed that the full system model predicts modes at frequencies in the region of maximum spectral response acceleration for typical design response spectra. An important contribution of this study regards the relative increase in higher mode response. It has been found that, for normal wind loading, 80 % of the tower energy is associated with the first mode, while, during the considered earthquake, the energy in the first mode is reduced to 54 % percent only of the tower energy, thus concluding that higher tower modes are more important for earthquake loading than for typical wind loading.

Another full model of HAWT has been proposed by Ishihara and Sarwar (2008). Starting from the observation that, unlike wind loads, seismic waves may excite a wide range of frequencies including those of higher modes, they have developed a nonlinear FEM code (CAST) for a full FE modeling of the HAWT and its components. Beam elements with a linear material have been used to model tower and blades. Analyses performed by the FE code on HAWTs, in a parked state, have been used in conjunction with the Japanese BSL response spectrum (BSL 2004) to derive design formula for the prediction of seismic loads on two turbines. In particular, following a semi-theoretical codified method provided by the Japan Society of Civil Engineering (JSCE 2007), a profile of seismic loads (shear and moment demand) acting on a HAWT in parked conditions was estimated from a base shear built as the sum of a shear force due the first mode, obtained by using the BSL acceleration response spectrum, and the shear force

contributions due to higher modes, obtained on the basis of the FE analysis. Results have been provided for two HAWTs, one with 400 kW rated power, 36 m hub height, and 31 m rotor diameter and the other one with 2 MW rated power, 67 m hub height, and 80 m rotor diameter. By comparison with the results obtained from time-domain simulations, it has been shown that the BSL 5 % damped response spectrum provides nonconservative seismic load profiles for both the 400 kW HAWT and the 2 MW one, thus confirming that a 5 % damping ratio is not appropriate for HAWTs in parked conditions, which experience much lower damping level. It is worth remarking that the time-domain simulations carried out by Ishihara and Sarwar (2008) highlighted that contribution of higher modes may become significant for large HAWTs (2 MW) under earthquake excitations, confirming similar results obtained by other researchers (Haenler et al. 2006).

Summary

The importance of seismic loading in the design of HAWTs is recognized in existing ISs and CGs, and in seismically active areas attention shall be paid to the possibility that design is driven by load combinations involving seismic excitations.

Existing methods for seismic assessment of HAWTs are fully coupled time-domain simulations, computing the response to simultaneously acting wind loading and seismic loading, and decoupled analyses, where the responses to wind loading and seismic loading are built separately and then superposed. Fully coupled time-domain simulations, although complex and time consuming, remain the indispensable benchmark tool for an accurate seismic assessment of HAWTs. However, decoupled analyses are also important, especially in the early stages of design.

For the implementation of fully coupled time-domain simulations, a full system model must be employed. Simplified models, where the rotor is not modeled, are allowed to build separate seismic loads in decoupled analyses.

Despite the prescriptions of existing ISs and CGs, a few important aspects are actively being investigated, such as the influence of SSI modeling, the importance of higher modes in the seismic response, the potential failure mechanisms under earthquake loading, and the estimation of aerodynamic damping for decoupled analysis. A full understanding of these aspects is desirable for a correct seismic assessment of HAWTs.

Introduction

Modern geophysical techniques enable changes to be observed at some volcanoes before magmatic eruptions: detection of seismicity (see “► [Seismic Monitoring of Volcanoes](#)”) from magma pushing through cold country rock is one of the most common and successful monitoring techniques and can lead to short-term

forecasting (see “► [Volcanic Eruptions, Real-Time Forecasting of](#)”). Another example of geophysical precursors to eruptions is surface deformation from inflation or deflation of a volcano due to magma movement. However, some volcanoes do not display these clues, and there remains a need for techniques that are sensitive to other physical attributes that might change in conjunction with the eruption process. Any overpressured magma storage reservoir, be it a system of dikes, sills, conduits, spherical chamber, or a combination of these, will exert a stress on the surrounding country rock that may or may not be manifest as observable strain. Detecting and understanding this stress may be a key to predicting if and when a volcano will erupt.

Definition

Seismic anisotropy is the variation of seismic wave speed with direction. It is an indicator of geometric ordering in a material, where features smaller than the seismic wavelength (e.g., crystals, cracks, pores, layers, or inclusions) have a dominant alignment. This alignment leads to a directional variation of elastic wave speed. Seismic anisotropy can be measured using many seismological techniques but is most frequently observed using shear wave splitting, which requires clear shear wave energy recorded on three-component seismometers. Measuring the effects of anisotropy in seismic data can provide important information about processes in the Earth such as stress conditions, material flow, and the structure of the subsurface and deep Earth.

Historical Background

Hess (1964) first made a significant observation of large-scale anisotropy when seismic refraction measurements in oceans showed that the P-wave velocity of the upper mantle (Pn) was consistently higher for profiles recorded perpendicular to an oceanic spreading center (i.e., parallel to the direction of spreading or plate movement) than for profiles recorded parallel to the spreading center. These measurements were attributed to the alignment of olivine crystals in the mantle lithosphere because of flow during the formation

Seismic Anisotropy in Volcanic Regions, Fig. 1 Shear wave splitting in an anisotropic medium. Anisotropy is caused by preferentially aligned cracks due to a maximum horizontal compressive stress (S_{Hmax}). A vertically propagating shear wave that is arbitrarily polarized gets split into a fast wave with polarization (ϕ) parallel to crack alignment and a slow wave, which is polarized at 90° to ϕ . The waves are separated with delay time δt

of the oceanic plate at the ridge. Since the 1970s, improvements in computing power and memory and in seismic field observation have led to a greater understanding of the seismic anisotropy of the Earth at all levels and scales (Savage 1999). Measurements of seismic anisotropy have been used to detect fabric and stress in the Earth's crust, flow in the upper mantle, topography of the core–mantle boundary, and differential rotation of the inner core.

The measurement of seismic anisotropy has been found to be a proxy for determining the direction of maximum horizontal compressive stress (S_{Hmax}) in the crust; applied stress can cause microcracks to preferentially open parallel to the maximum compressive stress, creating an anisotropic medium with the fast direction parallel to S_{Hmax} (Fig. 1). The mechanism of aligned microcracks is thought to be the only one that allows seismic anisotropy to vary on observable

timescales, and temporal changes are traditionally interpreted as stemming from variations in the stress field due to large earthquakes or magmatic intrusions. There is mounting evidence, however, that the dominant mechanism for seismic anisotropy can switch between a static condition, such as aligned fractures in fault zones, and a dynamic process, such as stress causing aligned microcracks to dilate. In areas where there are strong changes in S_{Hmax} direction and magnitude on observable timescales, such as at active volcanoes, seismic anisotropy analysis has proven a valuable tool when combined with ground deformation or other seismological observations for interpretation of volcanic processes such as magma migration (e.g., Gerst and Savage 2004; Bianco and Zaccarelli 2009; Unglert et al. 2011).

Seismic Anisotropy

Shear Wave Splitting

Shear wave splitting occurs when a shear wave travels through a seismically anisotropic medium, i.e., one in which seismic waves travel faster in one direction or with one polarization than another (Fig. 1). In the Earth's upper crust, anisotropy is most likely to be caused either by stress conditions preferentially aligning microcracks parallel to the maximum compressive stress or by pervasive structural features. For a near-vertical propagation direction, the shear wave with the displacement in the plane of the open cracks will travel faster than that crossing the plane of the cracks, and so a fast shear wave with orientation ϕ and a slow shear wave orthogonal to ϕ , separated by a delay time δt , will be observed (Babuška and Cara 1991). Crack-induced anisotropy has in some studies been considered a direct indicator of present-day stress, with ϕ providing information about the orientation of S_{Hmax} and δt giving information about the strength of anisotropy and the amount of time that the wave spent traversing the anisotropic medium. Studies that combine independent stress estimation methods with shear wave splitting results have found that strong geological fabric or aligned structures rather than the maximum

stress can govern the observed ϕ in some situations. Both stress-induced and structure-related anisotropies have been observed in the same regions and, in some cases, have been detected at the same station (e.g., Zinke and Zoback 2000; Johnson et al. 2011).

The subject of temporally varying anisotropy is a hotly debated topic (e.g., Crampin and Peacock 2008). Temporal variations in shear wave splitting can take the form of a rotation in the fast direction of anisotropy, an increase or decrease in the delay time, or a combination of both. The changes are thought to stem from perturbations of the elastic properties of the crust due to crack opening either by local concentration of shear stress or by a change in pore-fluid pressure. Monitoring these changes can therefore provide crucial information about the state of stress and pore content around active volcanoes. However, spatial variations of anisotropy masquerading as temporal variations are one of the main caveats associated with the interpretation (Johnson et al. 2011). This can occur when the location of the source earthquakes changes or migrates throughout the duration of the observation period leading to the seismic waves experiencing different anisotropic conditions due to heterogeneity in the anisotropic structure. Temporal variations in anisotropy associated with major magmatic eruptions, such as the 1995/1996 eruptions of Mount Ruapehu, have been subject to doubts about the possibility of shear wave splitting variations being due to changing source earthquake location. Therefore, the methods must be fully understood before changes in anisotropy with time can truly be used as an eruption forecasting tool. To do this, one must first explore the spatial variations in anisotropy at volcanoes before examining the temporal changes.

Mt. Ruapehu volcano in the North Island of New Zealand has been the subject of some of the most comprehensive shear wave splitting studies of any volcano on Earth. Therefore, to illustrate the spatial versus temporal variation issue, anisotropy studies at Mt. Ruapehu will be explored. Temporal variation of shear wave splitting at Mt. Ruapehu was investigated by Miller and Savage (2001) and Gerst and Savage (2004).

Miller and Savage (2001) measured shear wave splitting from earthquakes in 1994 and 1998 and observed a change in the dominant ϕ spanning the time of the last major magmatic eruption in 1995/1996. That study was extended by Gerst and Savage (2004), who used the same techniques and an additional deployment of three-component seismometers in 2002 to observe further changes in ϕ (Fig. 2). The results of both studies were interpreted as being caused by a dike-shaped magma reservoir, or system of dikes, trending NE–SW. According to this model, the magma reservoir was pressurized before the eruption, producing a local stress field different from the regional stress field. This interpretation is favored above one in which dikes are intruded and solidify, causing a new structural anisotropy, because of the lack of detectable deformation and seismicity associated with dike intrusion. The model suggests that following the eruption the reservoir was less full and correspondingly less pressurized, meaning that the local stress returned to that of the surrounding region. The Gerst and Savage (2004) study suggested that the later changes in ϕ were due to repressurizing of the reservoir in response to an increase of magma in the system because ϕ from deep earthquakes displayed the regional trend, while ϕ from shallow earthquakes was oriented to the pre-eruption direction. The return of anisotropy to the pre-eruptive state also supports the interpretation of stress-controlled anisotropy as the intrusion of dikes would be a permanent change.

Johnson et al. (2011) investigated the spatial variations in anisotropy in more detail using a dense seismometer deployment in 2008, to compare future changes in anisotropy and to identify the regions and causes of past changes in anisotropy with more confidence. Johnson et al. (2011) divided the mapped anisotropy into regions in which the fast polarizations agreed with stress estimates from focal mechanism inversions, suggesting stress-induced anisotropy, and those in which the fast polarizations were aligned with structural features such as faults or metamorphic fabric, suggesting structural anisotropy. Using this benchmark of anisotropy,

Seismic Anisotropy in Volcanic Regions, Fig. 2 Schematic stress and anisotropy model after Gerst and Savage (2004). In 1994, a pressurized dike system created a local stress field. In 1998, after the eruption, when the dike system was depressurized, stress directions partially returned to the regional trend. In 2002,

the dike system refilled, and the stress field in the anomalous region was dominated by the dike again. The alignment of cracks was not as strong as in 1994, so the anisotropy in the anomalous region was not strong enough to affect fast directions from deep events

Johnson and Savage (2012) examined temporal changes in shear wave splitting from 1994 to 2010. They observed a region of strong anisotropy centered on Mt. Ruapehu in 1995, the time of a major magmatic eruption, agreeing with Miller and Savage (2001) and Gerst and Savage (2004), which was interpreted to be due to an increase in fluid-filled fractures during the eruption. They also observed strong anisotropy and a change in fast direction ($\sim 80^\circ$) at Mt. Tongariro in 2008, which was initially interpreted to be due to a change in the geothermal system but was later the location of a small eruption in 2012.

Measuring Shear Wave Splitting

Many methods have been developed to measure shear wave splitting in the Earth's crust (e.g., Crampin and Gao 2006). The goal is to identify the orientation of the fast split shear wave and the delay time between the fast and slow split shear waves. These parameters can then be used to infer rock properties such as crack distribution and

geometry, pore content, or stress regime. Ideally, the procedure will be able to accurately process large quantities of three-component data in an efficient, unbiased, and objective way, without operator intervention, while providing quantitative evaluation of the uncertainties for each measurement of shear wave splitting.

A manual method for analyzing shear wave splitting is that of direct inspection of the 3D particle motion projected onto a horizontal plane (hodograms). This method relies heavily on observer judgment and therefore can produce biased results and is inefficient for large datasets. Other methods employ partially automated programs, where the user must pick a window around the shear wave arrival and/or evaluate the results. There are several approaches commonly used to semiautomatically determine shear wave splitting parameters: the covariance matrix technique searches for nonzero eigenvalues to "unsplit" the shear wave; the cross-correlation technique searches for the rotation

and time delay that yields the highest cross-correlation between orthogonal components; the aspect ratio technique searches for the rotation and time delay that yields the most linear particle motion with the maximum aspect ratio; and the vector amplitude technique uses the maximum amplitude in a time window to identify the split shear waves. Any degree of user interaction may introduce some subjectivity and is usually time-consuming, although many practices of automated quality control will result in loss of significant amounts of data. Completely automated shear wave splitting analysis has proven elusive, as the step that is difficult to automate is the picking of the shear wave arrival. Several methods boast full automation other than this problematic step. In general, since phase arrivals are often picked for previous analyses such as hypocenter location, these automated methods are preferable to the ones with a lot of user interaction; more data can be evaluated, reducing the effect of loss of data through the quality control steps.

Interpreting Shear Wave Splitting: Some Assumptions

Most shear wave splitting observations are interpreted under some assumptions, which are rarely completely true in the Earth:

1. **That the medium possesses hexagonal symmetry with a horizontal axis:** The majority of anisotropic rocks in the Earth have, or can be approximated to have, hexagonal symmetry. This is because the most common symmetries have patterns that do not differ significantly for horizontal fast axis alignment and near-vertical incidence angles. The simplest models used to explain variations in two orthogonal directions are hexagonally symmetric models. Therefore, shear wave splitting is usually interpreted in terms of transverse anisotropy with a horizontal symmetry axis.
2. **That the anisotropic medium is in a single, homogeneous layer:** When a shear wave passes through multiple anisotropic layers, the observed splitting parameters depend strongly on the thickness and strength of anisotropy of the layers, on the relative fast directions, and on the wavelength of the wave. If the shear wave has been sufficiently split in the first layer that the fast and slow waves are separated, then when it enters the second layer, which has a fast direction 20–70° different, both of the quasi-shear waves will be split again. In this case both waves will now have the fast and slow directions of the second layer. However, when the splitting from the first layer is weak so that the two quasi-shear waves are not more than one wavelength apart, both waves are still resplit, but the result is a complex waveform that is difficult to interpret but can still be meaningful. In general, shear wave splitting fast direction is representative of the last layer that the wave passed through and the delay time can be approximated as accumulating along the path.
3. **That the anisotropic medium is localized beneath the receiver:** As seen in the previous point, in general, the anisotropy parameters are representative of the last anisotropic medium that the wave travelled through. Therefore, the assumption that the medium is local to the station is usually justified. However, in regions with heterogeneous anisotropic structure, data at a single station will not be consistent and the assumption will not be appropriate.

Further discussions of these points can be found in Silver and Savage (1994), Savage (1999), and Johnson et al. (2011).

Other Estimates of Seismic Anisotropy

Shear wave splitting analysis is becoming a very popular method for determining seismic anisotropy in the crust. This is in part due to the abundance of data and methods available and also to the relative insensitivity to the source–receiver geometry (other than deep enough earthquakes for the rays to arrive within the shear wave window) and independence from the need for dense networks of seismometers (see “► [Seismic Network and Data Quality](#)”). Another benefit of

shear wave splitting analysis is that, even though the results can be averaged over multiple measurements, they represent a snapshot of anisotropy. There are, however, other methods for determining seismic anisotropy. Most of the other methods involve calculating anisotropic velocities using tomographic techniques (see “► [Seismic Tomography of Volcanoes](#)”) with body or surface waves from active or passive sources, or using ambient seismic noise (see “► [Noise-Based Seismic Imaging and Monitoring of Volcanoes](#)” and “► [Seismic Noise](#)”).

Tomographic methods (see “► [Seismic Tomography of Volcanoes](#)”) require larger amounts of data with relatively even coverage of sources and sensors, which (usually) take longer to acquire, thereby rendering the methods less practical for time-lapse investigations than shear wave splitting investigations. Tomographic methods that are used to calculate seismic anisotropy are different to techniques that conduct tomographic inversions on shear wave splitting data. Anisotropy parameters are derived from the inversions in the former case, while the latter is an inversion of the anisotropy parameters.

Inversions of body wave arrival times for three-dimensional velocity structures are common practice at volcanoes using teleseismic waves, local earthquake sources, and active seismic sources. These inversions can also account for 3D V_p azimuthal anisotropy, which is parameterized with a percent anisotropy and an orientation of the fast axis. Seismic anisotropy can be detected using inversions of Love and Rayleigh surface waves from large earthquakes in the same manner.

Surface waves constructed from cross-correlations of ambient seismic noise can be inverted for 3D seismic velocity structure. Seismic anisotropy from ambient noise tomography can be calculated. These calculations are different from the time-lapse studies that detect temporal variations in isotropic seismic velocities using ambient noise interferometry (see “► [Tracking Changes in Volcanic Systems with Seismic Interferometry](#)”).

Variations in Shear Wave Splitting

Spatial Variation of Shear Wave Splitting

Most shear wave splitting results are plotted as rose diagrams (circular histograms) of fast direction at the station at which the measurements were made (e.g., Fig. 2). This implicitly assumes that the anisotropy is localized beneath the station. In many regions this may be appropriate; however, when there is lateral heterogeneity, the rose diagrams will become scattered or multimodal. Johnson et al. (2011) detected distinct splitting parameters for measurements using earthquakes from several different clusters in the region of Mt. Ruapehu. This backazimuthal dependence implies that the ϕ value obtained from shear wave splitting analysis is highly dependent upon the path that the ray takes, which has also been found in other regions. Furthermore, this suggests that the anisotropy changes over shorter distances in the crust than is often observed for mantle anisotropy and that averaging ϕ over the whole region may not be appropriate. If the causes of the different regions of anisotropy are known, it is easier to identify and map the differences using shear wave splitting analysis. If the crustal stresses or fabrics are more complex or unknown, then it is more difficult to map and interpret heterogeneous anisotropy, although a denser array of seismic stations and a broad range of backazimuths increase the likelihood of identifying the source of heterogeneity.

For time-lapse studies, it is important to mitigate the chance of spatial variations of shear wave splitting being erroneously interpreted as temporal variations. One way to do this would be to map spatial variations in detail at a time when there are no hypothesized temporal changes. This becomes difficult, but essential, when the anisotropy is very heterogeneous and the seismograph array is less dense than the spatial changes. This section outlines some examples of shear wave splitting tomography studies, which attempt to solve the problem of spatial variation.

Shear wave splitting tomography is difficult because of the nonlinear effect of multiple layers

Seismic Anisotropy in Volcanic Regions, Fig. 3 Delay time tomography from the inversion of shear wave splitting data at Mount Ruapehu Volcano, New Zealand. Warm colors indicate strong anisotropy,

shaded area shows the limit of statistical significance calculated from the model variance matrix, white inverted triangles are seismic stations (After Johnson et al. (2011))

of anisotropy on waveforms. This is different to travel time tomography, in which the travel time of a wave is often linearly related to the velocity structure of the media it has passed through. Because of this difficulty, many techniques treat ϕ independently from δt . Three-dimensional tomographic inversions can be carried out on the delay time data to characterize fracture density distribution. This tomography uses only δt from local earthquakes to investigate anisotropy strength in the crust. In this way, regions of high anisotropy can be identified, but information regarding fast directions is not accounted for.

Audoine et al. (2004) presented a simple method of 2D spatial averaging to examine heterogeneous anisotropy in the crust. A grid was

constructed with nodes regularly spaced between each earthquake and station. This grid was then treated as a new dataset, and ϕ for each node within a polygon, or within a box of a regular lattice, was averaged. This created average ϕ values at regular intervals that could be denser than the station spacing, hereby identifying spatial trends in fast directions, but not accounting for delay times. Johnson et al. (2011) adapted a combination of the above methods to map the heterogeneous seismic anisotropy field around Mt. Ruapehu in New Zealand (Fig. 3). To constrain the locations of high anisotropy, they conducted a two-dimensional tomographic inversion on the delay time estimates. They then used a spatial averaging technique similar to that of

Audoine et al. (2004), but with the fast polarizations weighted according to the strength of anisotropy calculated from the tomography. The method uses a quad-tree gridding system to enable higher resolution where the data permit and couples the two shear wave splitting parameters, even though they are not used in a joint inversion.

Abt and Fischer (2008) carried out full 3D shear wave splitting tomography for the mantle. The method parameterized the mantle as a 3D block model of crystallographic orientations. Nonlinear properties of shear wave splitting were accounted for by applying the inversion iteratively and recalculating partial derivatives after each iteration. Using this method, Abt and Fischer (2008) modeled an idealized subduction zone with uniform stations and sources. When applied to real data, they found that the geometry of stations and observed seismicity in the Nicaragua–Costa Rica subduction zone yielded partial to good resolution. This method also has the potential to be applied to crustal studies such as active volcanoes.

Temporal Variation of Shear Wave Splitting in the Crust

The temporal variation of shear wave splitting and its interpretation is highly controversial. The main point of dispute is whether the accumulation of stress before significant events such as eruptions or large earthquakes allows the time and magnitude of impending events to be stress forecast through shear wave splitting monitoring. The effects have been reported with hindsight before at least 15 earthquakes. Crampin and Peacock (2008) present a summary of observations of temporal variations in shear wave splitting attributed to stress-aligned fluid-saturated microcracks. However, alternative interpretations of these observations of temporal changes suggest there may be observer bias in data selection, unsound statistical analyses, misinterpretation of spatial variation, and lack of correlation with other stress-determining factors/correlation with structural evidence.

Clear evidence has been obtained that crustal shear wave splitting can vary over short distances and can be caused by structural features in the

crust, which would not change with changing stress. However, it is also clear that anisotropy due to stress-aligned fluid-saturated microcracks can change with time, as has been demonstrated in industry when small changes associated with injection and removal of fluids from reservoirs were examined. The use of similar earthquakes (i.e., those that have the same source mechanism and location) for shear wave splitting analysis helps to eliminate some of the discrepancies with interpretation. Johnson et al. (2010) used shear wave splitting analysis, a multiplet of 25 similar earthquakes and double-difference relocation to examine temporal variations in seismic properties prior to and accompanying magmatic activity associated with the 2008 eruption of Okmok Volcano. They found a general change in ϕ but could not rule out dependence on backazimuth and no significant change using the multiplet. Using earthquakes originating from the subducted slab in order to reduce the effect from changing paths, several modes of ϕ were identified, relating to the anisotropy of the mantle wedge, regional stress direction, and local stress induced by the pressurization and depressurization of the magma reservoir. These modes were found to have different prominence at different times throughout the eruptive cycle.

Once again returning to the example of Mt. Ruapehu, Miller and Savage (2001) and Gerst and Savage (2004) observed general changes in seismic anisotropy throughout the eruptive cycle. Johnson et al. (2011), however, showed that seismic anisotropy around Mt. Ruapehu is heterogeneous and that averaging the whole region is not appropriate. Therefore, Keats et al. (2011) used seismicity generated from a consistently active area of seismicity about 20 km to the west of Mt. Ruapehu. Shear wave splitting results revealed a decrease in delay time in the 2006–2007 eruption period and a significant variation in the fast shear wave polarization in the same time period (Fig. 4). These changes were attributed to an increase in pore-fluid pressure in the region due to fluid movement, and it was suggested that this fluid movement may be associated with the eruptions in 2006 and 2007.

Seismic Anisotropy in Volcanic Regions, Fig. 4 Moving average plot of fast polarization (ϕ) and delay time (δt) using earthquakes within the Erua swarm at station FWVZ at Mount Ruapehu, New Zealand. Individual measurements for ϕ and δt are displayed in light blue and 10-point moving averages are displayed in dark blue. The error bars indicate 95 % confidence intervals. The four time periods, marked by the numbers 1–4, and three transition zones, marked by a t, are indicated with vertical red lines and the mean for each period are shown

by the red horizontal bars with 90 % confidence interval (dashed red lines). The times of the two phreatomagmatic eruptions that occurred are also marked with grey bars. Rose diagrams of ϕ are displayed in their respective time periods. The b-value for the Erua swarm catalogue is also plotted against time in black at the top using a window of 40 events and an eight-event overlap. Dashed black lines indicate 95 % confidence interval (After Keats et al. (2011))

Temporal variation of shear wave splitting parameters as a stress indicator has been employed at several other volcanoes. While most studies concentrate on either stress-induced anisotropy or structurally dominated anisotropy, several studies have found that the dominant mechanism can change between the two (Keats et al. 2011; Johnson and Poland 2013) and that more than one mechanism can be dominant over short distances, potentially creating an apparent temporal change that is actually an artifact of changing earthquake location (Zinke and Zoback 2000).

Even though we have seen that shear wave splitting analysis can be used as an indicator of stress and of fluid saturation in the crust, surprisingly few studies have been conducted on shear

wave splitting around volcanoes (Fig. 5). This is due, in part, to the generally noisy waveforms and complicated interpretation of such observations when taking into account heterogeneity and complex stress regimes. It should be noted that there is significant literature about shear wave splitting in the mantle beneath active volcanoes because these regions are invariably of interest tectonically, but this entry focuses on crustal studies only.

Relating Shear Wave Splitting to Other Observations

Shear wave splitting analysis has been proven to be a useful indicator of stress and of fluid

Seismic Anisotropy in Volcanic Regions, Fig. 5 Map showing volcanoes at which shear wave splitting investigations have been carried out. *Green volcano symbol*

indicates that temporal variations were observed, *red* indicates that no temporal variations were observed

saturation in the crust but can also be caused by structures such as macroscopic fractures or mineral alignment. At volcanoes, the generally noisy waveforms, complicated heterogeneity, and complex stress regimes can make interpretation of shear wave splitting difficult. For this reason, shear wave splitting investigations are often coupled with other stress or strain indicators and structural geology data to minimize the ambiguity in the interpretation.

Volcanic Seismicity, Fault Plane Solutions, and b-Value

Studies of shear wave splitting in areas of developed industry may use direct indicators of the stress field in the crust, such as borehole break-outs, for comparison with shear wave splitting results. However, few active volcanoes have these clues, so other stress monitoring techniques must be employed.

The occurrence of volcano-tectonic (VT) (see “► [Volcano-Tectonic Seismicity of Soufriere Hills Volcano, Montserrat](#)”) earthquakes is an immediate indicator of differential stress in the crust around a volcano. Changes in the stress field may trigger more VTs, the detection of which is one of the most successful tools of seismic

volcano monitoring. For this reason, many shear wave splitting studies have been designed to investigate temporal changes in anisotropy during a volcanic crisis (e.g., Savage et al. 2010; Johnson et al. 2010; Roman and Gardine 2013). Bianco and Zaccarelli (2009) calculated a background seismic anisotropy at Mount Vesuvius of 4 %, but at times of seismic crisis, the average anisotropy was 8 % and the fast directions tended to flip by 90°.

As noted above, however, heterogeneity in the anisotropic media must be carefully considered, especially when there is a migration of seismicity associated with magma movement. These migrating earthquakes are used as sources of shear wave energy, but temporal variations observed in the anisotropy measurements could be due to spatial variations.

VT earthquakes contain additional information about the state of stress in the crust. Fault plane solutions (FPS) provide information about the orientation of the fault plane that slipped, as well as the slip vector for each earthquake. From the FPSs, the pressure and tension axes can be identified, which give information about the stress regime. The FPS P-axis azimuth, which represents the orientation of the principal

compressional axis of the moment tensor, may in reality differ significantly from the orientation of maximum compressive stress, depending on the orientation of preexisting planes of weakness (faults). This is sometimes countered by calculating large numbers of FPS P-axis azimuths to highlight the major trends that most likely represent the actual orientations of S_{Hmax} (e.g., Roman and Cashman 2006; Roman and Gardine 2013). Another step can be taken by inverting for the full stress tensor using the FPS results (e.g., Johnson et al. 2011). The true direction of S_{Hmax} can then be compared with shear wave splitting parameters to jointly interpret the results.

The orientations of FPS of VT earthquakes have been observed to display systematic changes related to episodes of magmatic activity at several volcanoes (Roman and Cashman 2006). The pressure axes of FPS have been observed to rotate orthogonal to the dominant regional stress orientation in some cases, indicating that these earthquakes may result from dike inflation in the direction of minimum compressive stress (Roman and Cashman 2006). Roman and Gardine (2013) investigated shear wave splitting and earthquake fault plane solutions at Redoubt volcano around the time of the March 2009 eruption. They found that an approximately $\sim 90^\circ$ change in the polarization of shear wave splitting fast polarization accompanied the earliest signs of seismic unrest in 2008 and continued through the eruption before diminishing in 2009. A similar change in the orientation of fault plane solutions occurred 18–48 h prior to the eruption onset on March 23, 2009, but almost 2 months after a strong increase in the rate of shallow VT earthquakes. The shear wave splitting and FPS results suggested a protracted period of slow magma ascent followed by a short period of rapidly increasing magma pressurization beneath the volcano. Roman and Gardine (2013) found that after the eruption, both shear wave splitting fast polarization and fault plane solution pressure axes had a direction more consistent with the regional stress than before the eruption.

The b-value of a cluster of earthquakes is often used to describe the size distribution. The b-value

comes from the Gutenberg–Richter law and is a frequency magnitude (see “► [Frequency-Magnitude Distribution of Seismicity in Volcanic Regions](#)”) relation. For crustal earthquakes, b-values are typically ~ 1 for tectonic earthquakes, though they tend to be higher in volcanic regions (see “► [Frequency-Magnitude Distribution of Seismicity in Volcanic Regions](#)”). The b-value has been related to physical properties such as stress, material homogeneity, and pore pressure and can therefore be useful in comparison with seismic anisotropy measurements to determine changes in physical properties around volcanoes. Keats et al. (2011) used seismicity from a discrete cluster of earthquakes near Mt. Ruapehu in New Zealand to compare shear wave splitting and b-values over 12 years (Fig. 4). The joint analysis allowed them to attribute temporal changes to an increase in pore-fluid pressure due to fluid movement associated with eruptive activity.

Attenuation, V_p/V_s Ratio, and Noise Cross-Correlations

Perturbations of the elastic properties of the crust around volcanoes are often linked to crack opening either by local concentration of shear stress or by an increase of pore-fluid pressure. Shear wave splitting analysis is one way to monitor these properties, but there are other techniques that can provide additional information about the state of stress or pore content. Earthquake coda (the part of a high-frequency seismogram following the P and S waves) is generated by random scattering processes in the crust. The coda decay parameter (or Q_c^{-1}) is often used to parameterize characteristics of the medium, and temporal changes in Q_c^{-1} have been linked to crack opening (Del Pezzo et al. 2004).

Increased gas content in pores and cracks has the effect of lowering P-wave speed due to the higher fluid compressibility, but not significantly affecting the shear modulus and hence S-wave speed. The ratio between P-wave velocity (V_p) and S-wave velocity (V_s), V_p/V_s , is therefore useful for characterizing pore-fluid content. Gas-enriched pore space has been reported to affect V_p/V_s above magmatic intrusions and has

been combined with shear wave splitting studies to characterize pore content at volcanoes (Unglert et al. 2011; Johnson and Poland 2013).

The perturbations of the elastic properties of the crust around volcanoes caused by changes in stress or pore fluid can be monitored continuously using cross-correlations of ambient seismic noise (see “► Noise-Based Seismic Imaging and Monitoring of Volcanoes” and “► Seismic Noise”). Monitoring of Q_c^{-1} , V_p/V_s ratio, and isotropic velocity from seismic noise cross-correlations therefore naturally complements shear wave splitting investigations as the mechanisms of change are so similar (Del Pezzo et al. 2004).

Deformation

Geodetic techniques that determine changes in strain, such as GPS and InSAR, can provide some of the stress tensor elements and can therefore be useful to compare with shear wave splitting investigations. Studies such as those by Savage et al. (2010) and Unglert et al. (2011) use strain data to determine that the anisotropy is due to stress-oriented microcracks in the upper crust. At Mount Asama, Savage et al. (2010) correlated GPS baseline length measurements with shear wave splitting measurements to analyze stress changes accompanying the eruption in 2004. They found that the best model from the GPS analysis of a vertical dike and conduit also fit the shear wave splitting measurements, as did the temporal variations. From this, a crack aspect ratio of 2.6×10^{-5} was calculated and a differential horizontal stress of 6 MPa at 3 km depth was inferred. Unglert et al. (2011) performed shear wave splitting analyses on local earthquakes around Aso Volcano between 2001 and 2008 and compared the results to strain from GPS measurements in the area. They observed, using clusters with relatively stable epicenters, that two stations showed a significant change in ϕ in 2004–2005. Models from seismic tomography and receiver functions were found to fit both the anisotropy and strain measurements. Other studies have used the observations of no correlation between geodetic measurements and shear wave splitting results to infer that the mechanism of anisotropy is structurally

controlled. An anticorrelation between geodetic measurements and shear wave splitting results was observed at Kīlauea Volcano, implying that some volcanic process was affecting both measurements but that the mechanism was different to the traditional interpretation of a pressurizing magma reservoir. Johnson and Poland (2013) used these observations, combined with V_p/V_s ratio to interpret these changes as being due to increased gas flux.

Geology

Numerous investigations have found that in some regions, the fast direction of anisotropy is oblique to the direction of maximum horizontal compressive stress. In these cases, other clues for the cause of anisotropy are sought and the anisotropy is frequently found to align preferentially with macroscopic structures at the surface. Macroscopic fractures are often aligned because they are caused by faulting in a regional stress field. These macroscopic structures also cause anisotropy and shear wave splitting that often aligns with S_{Hmax} . Exceptions arise when strike-slip faults initially align at 45° to the direction of S_{Hmax} , faults are a product of a paleostress, or the rock has been deformed since the faulting. Velocity anisotropy is also strongly dependent on rock fabrics and metamorphic rocks with distinct foliations can have anisotropies of up to 20 % even in the absence of cracks (Babuška and Cara 1991, and references therein). This is mainly due to the preferred alignment of intrinsically anisotropic minerals such as biotite and hornblende. Geological textures can be identified through analysis of in situ rocks or oriented drill cores. Shear wave splitting that is caused by structural features is unlikely to change over time periods of investigation. However, due to changing conditions in stress or pore content, the dominant mechanism of anisotropy can change, rendering a temporal variation in shear wave splitting parameters. Johnson and Poland (2013) investigated shear wave splitting changes at Kīlauea Volcano associated with the onset of the summit eruption in 2008. They found that the orientation of fast shear waves at Kīlauea was usually controlled by structure, but in 2008 showed changes

with increased SO₂ emissions preceding the start of the summit eruption.

Tectonic Versus Magmatic Stress-Controlled Anisotropy

Studies that have recorded rotations in the fast direction of anisotropy due to a localized perturbation in stress often relate the background stress regime to the regional tectonics of the area. Rotations of ϕ by 90° are commonly observed, but several mechanisms for the rotation have been proposed. The 90° rotations should be treated carefully because cycle skipping, when the match of the fast and slow waveforms has a factor of T/2 ambiguity where T is the dominant period, can lead to an error of 90° in the recorded fast direction and a false delay time. When the rotations are real, Crampin et al. (2002) suggest that they are “flips” caused by wave propagation through cracks containing fluids at high pore-fluid pressures. However, a 90° rotation would also be expected due to a dike intrusion (Gerst and Savage 2004). A dike will exert pressure on the surrounding rock, generating a local stress field that is superimposed on the regional stress field. The stresses of such an elongated structure are mainly oriented perpendicular to the strike axis. When the pressure in the dike system is high enough, the generated stress field locally reorients the principal stresses as well as the local crack alignment. The pattern of stress perturbation around an intrusion can be complex, however, and the interaction with the regional, or tectonic, stress has been the subject of several studies (e.g., Roman and Cashman 2006; Vargas-Bracamontes and Neuberg 2012). Vargas-Bracamontes and Neuberg (2012) found that in the presence of a dominant regional stress field, the stress perturbation from an intrusion will be negligible. As the pressure from the intrusion increases, both the regional and the local stress field will coexist. This phenomenon was observed at Okmok Volcano, Alaska, when the shear wave splitting results displayed a mode corresponding with the regional stress direction and one corresponding with the pressurization of the magma reservoir (Johnson et al. 2010). As the pressure is progressively increased,

Vargas-Bracamontes and Neuberg (2012) found that the stress patterns gradually approach those corresponding to the absence of a regional stress field. Therefore, in cases with extremely high magma pressures, such as before large explosions at Soufriere Hills Volcano, Montserrat, the regional stress field may be omitted in numerical models.

The Future of Seismic Anisotropy in Volcanic Regions

Using seismic anisotropy to measure stress at active volcanoes holds enormous potential as a monitoring and eruption forecasting tool. Changes in seismic anisotropy associated with volcanic activity have already been detected; however, interpretation of seismic anisotropy observations is usually qualitative, and researchers struggle to use the results to quantify the magnitude of stress variations and the cause. Eruption forecasting is increasingly evolving from empirical pattern recognition to forecasting based on models of the underlying dynamics. For shear wave splitting monitoring to be beneficial, physical models must be developed that can explain not only changes in general trends but also the scatter in the data and anomalous observations. Central to this are the links between stress changes and fracture or crack compliance in the country rock and the role that fluids in cracks play, particularly the effects of hydrothermal circulation, pore pressure, and gas flux. Another limitation is that the majority of current research seeks to interpret only ϕ or only δt observations, but the two parameters are inherently linked. Models used to explain shear wave splitting observations must predict both parameters.

To quantify the response of seismic anisotropy to pre-, co-, and post-eruption subsurface magma movement, shear wave splitting data should first be used to map the areas affected by changing stress and identify the mechanism of seismic anisotropy in areas that do not have stress-controlled anisotropy. Methods have recently been developed for the inversion of

geomechanical parameters such as crack size, geometry, density, and content (e.g., Wuestefeld et al. 2012). Monitoring of these properties over time will not only indicate the occurrence of changes but will elucidate the nature of the subsurface changes.

Increasingly realistic numerical and experimental models of the fluid dynamics and elastodynamics are becoming possible. Integration of multidisciplinary data within these models will enable greater understanding of the underlying mechanisms and may be used to calculate the shear wave splitting and other important parameters for different volcanic scenarios. Ultimately, it may be possible to use information contained in seismic anisotropy to monitor subsurface magma movement and forecast changes in a volcano's behavior by establishing the characteristic stress field response for a given volcano, or through a deeper understanding of the complex relationships between seismic anisotropy, local crustal stresses, and the physical mechanisms of magma migration.

Summary

Seismic anisotropy is the variation of seismic wave speed with direction. Shear wave splitting occurs when a shear wave travels through a seismically anisotropic medium. Temporal variations in shear wave splitting can take the form of a rotation in the fast direction of anisotropy, an increase or decrease in the delay time, or a combination of both. The measurement of seismic anisotropy has been found to be a proxy for determining the direction of maximum horizontal compressive stress in the crust; applied stress can cause microcracks to preferentially open parallel to the maximum compressive stress, creating an anisotropic medium with the fast direction parallel to the maximum horizontal compressive stress. The mechanism of aligned microcracks is thought to be the only one that allows seismic anisotropy to vary on observable timescales, and temporal changes are traditionally interpreted as stemming from variations in the stress field due to large earthquakes or magmatic intrusions.

The changes are thought to stem from perturbations of the elastic properties of the crust due to crack opening either by local concentration of shear stress or by a change in pore-fluid pressure. There is mounting evidence, however, that the dominant mechanism for seismic anisotropy can switch between a static condition, such as aligned fractures in fault zones, and a dynamic process, such as compressive stress causing aligned microcracks to dilate. In areas where there are strong changes in maximum compressive stress direction and magnitude on observable timescales, such as at active volcanoes, seismic anisotropy analysis has proven a valuable tool when combined with ground deformation or other seismological observations for interpretation of volcanic processes such as magma migration. By inverting shear wave splitting data for geomechanical parameters and integrating the results with numerical and experimental models, it may be possible to monitor subsurface magma movement.

Introduction

The earthquake occurred on April 6, 2009, in Italy at L'Aquila has been a catastrophic event for both the city and the University of L'Aquila (Ceci et al. 2010). Since then, numerous scientific activities have accompanied both the immediate recovery and the long reconstruction program in different fields of earthquake science and engineering. In particular, the development of new

systems and technologies for both understanding and enhancing the structural behavior of significant historical palaces and churches, densely populating the L'Aquila city center, has attracted the attention of specialists and researchers coming from a broadband spectrum of scientific disciplines. This rich multidisciplinary approach has permitted the development of a new paradigm in the preparatory works necessary for planning the retrofitting and the reconstruction of ancient buildings. Therefore, the impact of new technologies in the area of observation, survey, testing, modeling, restoration, retrofitting, and monitoring of historic constructions and monuments, diffusely used at L'Aquila, merits to be discussed and briefly reported, here, as starting point for future novel findings and process optimization.

In this respect, it appears reasonable to mention the geophysical and geotechnical research efforts conducted to characterize various aspects of what has been observed and measured during foreshock, mainshock, and aftershock in the L'Aquila valley. Starting from a historical seismological study regarding the earthquakes that took place in the area of L'Aquila (central Italy) from the ancient Roman period to the late Middle Ages, the persistence and magnitude of earthquakes demonstrated to have a strong bearing on the economy and culture of the communities (Guidoboni et al. 2012). Furthermore, understanding the rupture slip distribution for the 2009 L'Aquila mainshock has allowed for the development of a complex high-resolution 3D FE model incorporating surface topography and rheological heterogeneities, deduced from real tomography (Volpe et al. 2012). The 3D approach provides a more concentrated and localized slip distribution on the rupture plane, evidencing a single area of high-slip release SE of the hypocenter. Moving from the underground level to the ground level, scientific studies have tried to correlate the distribution and the severity of the damage with the geological setting of the area, taking into account the characteristics of the building stock through time (Tertulliani et al. 2012). Strong-motion records and ambient noise measurements taken soon after the mainshock and during the entire aftershock

sequence showed variability in ground motion amplification throughout the city. General conclusions highlight that the building stock of the city suffered different levels of damage that can be partially explained by the combination of building vulnerability and surface geology. In particular, the observation of damages in RC buildings highlighted that the few collapse cases ($<1\%$ of the whole RC buildings stock) are mainly the consequence of structural deficiency, inadequate structural layout, and maybe site effects (Decanini et al. 2012). The majority of RC construction survived the earthquake with minor damages or with damages to nonstructural elements. The extensive observed damage to infill walls that can be associated to a significant amount of energy dissipation prevented the development of plastic hinges in RC columns, thus allowing the maintenance of structural integrity. Concerning the seismic demand, the study highlighted the noticeable difference between the elastic and inelastic demand, indicating that the displacement demand is moderate, associable to a non-extraordinary event, even if, in several cases, it overcomes the threshold of serviceability limit, producing economic losses and potential injuries and deaths (Ceci et al. 2013).

Much more complex than the damage scenario affecting the RC buildings is the case of technical observations made on which occurred specifically in historic constructions and monuments at L'Aquila (D'Ayala and Paganoni 2011; Da Porto et al. 2012; Indirli et al. 2013) and in the small historical centers of the valley (D'Ayala and Paganoni 2011; Carocci 2012; Indirli et al. 2013). These studies show that within the historic city center of L'Aquila, the number of total collapses observed was minor, while the proportions of partial collapses of the upper stories were perhaps greater than would have been expected given the level of shaking (D'Ayala and Paganoni 2011). In a minority of cases, total collapse of the facade was observed, and these were usually associated to substantial alteration of the original structure. Although the number of undamaged masonry buildings is very modest, the majority suffered either minor damage or repairable structural damage.

This situation allowed on one hand to identify and recognize collapse mechanisms and on the other hand to better correlate ultimate capacity to strong-motion characteristics and hence lends itself to a more detailed in situ survey and analytical assessment. In the specific case of churches, a statistical analysis has defined the percentages of possible mechanisms related to local construction practices and architectural features of the region. For each possible mechanism, the relative percentage of activation and calculated average damage allowed some conclusions to be drawn on the seismic vulnerability of the various structural and nonstructural elements making up a church. These conclusions may be regarded as widely valid and, if further corroborated by other post-earthquake surveys, may be used to define hierarchies of interventions, also on non-damaged structures (Da Porto et al. 2012). The study showed that it would be useful to introduce weights to damage mechanisms when calculating damage indices evaluated through survey form compilation, which is still a powerful tool in the management of emergency and post-emergency phases. Furthermore, it has been pointed out that the recorded high-peak ground accelerations reached high values, both in the horizontal and vertical directions. The simultaneous combination of these acceleration components, has produced a reduction of the masonry shear capacity, especially in the upper floors. Consequently, the widespread vulnerability of unreinforced masonry buildings resulted in extensive damage, collapse, and victims in a medium-size city. The underestimation of the earthquake actions is a considerable drawback that can be overcome only by integrating the study of earthquake scenarios with more accurate methodologies. Moreover, with regard to the structural vulnerability, most of the unreinforced masonry structures were built (and structurally modified with subsequent interventions) before the adoption of the 2002 updated requirements; thus, the percentage of unreinforced masonry buildings heavily damaged or collapsed in the epicenter area is relatively high (approximately 45 %). The first cause of widespread overall disruption originates from the very poor quality

of the disaggregated masonry, made by arbitrary materials, unable to resist horizontal forces. Several damage/collapse types have been encountered, classified, and associated with the simplified mechanisms foreseen by the Italian MEDEA procedure (Indirli et al. 2013).

The needs of simplified performance-based assessment procedures in order to support the interpretation of observed damage is evidenced in all recent earthquakes, such as those occurred in L'Aquila (2009), Christchurch (2010–2011), and Emilia Romagna (2012), which have caused not only a significant death toll and huge economic losses but also heavy damage to the worldwide cultural heritage (Parisi and Augenti 2013). Earthquake damage to monumental constructions has been discussed and critical issues affecting the seismic response of historic masonry structures are identified such as masonry quality, connections among structural elements, diaphragm flexibility, out-of-plane resistance of masonry walls, structural irregularities, wrong retrofit interventions, and earthquake ground motion characteristics.

Moreover, since 2009, the reconstruction idea of the city of L'Aquila and its surrounding was a main goal, primarily of the citizens and, with them, of the Italian Government. However, during every catastrophic earthquake, Italian citizens and institutions seem to face a series of typical problems due to bureaucratic burdens, corruption, excess legislation, political clientelism, poor performance, and weak public control, and they are the combined effects of cultural, institutional, and political factors at the governance level (Özerdem and Rufini 2013).

Notwithstanding several difficulties, numerous applied research activities have been conducted in the area of new and sophisticated methods for the assessment of masonry complex structures, which need retrofitting interventions. Most of the works conducted at L'Aquila in this area are characterized by a series of correlated activities ranging from historic search, survey, and analysis of the structure with regard to proposals for repair and seismic strengthening. In particular, several problems are generally encountered in the various levels of survey and

damage interpretation and those of modeling and analysis of the structural behavior of complex and clustered masonry buildings (Da Porto et al. 2013). The in-depth comparative studies between the surveyed damages and the results of structural assessment through different approaches have produced a great enhancement in the understanding of the complex behavior of masonry structures, evidencing that use of the “Natural Laboratory of Earth” is the best approach to evaluate the seismic behavior and the performance of structural systems as well as the failures occurring in reality and is a non-substitutable step for the advancement of knowledge in the field of seismic engineering (Brandonisio et al. 2013). For example, the observation made on large historical palace, such as the case of Palazzo Centi, has shown that, during the 2009 earthquake, differently from other historical masonry buildings, it responded “reasonably” well in the main structural parts also due to recent retrofit interventions carried out in 2003. These mechanical interventions proved to be the reason of the good seismic behavior of the building and that “saved” it from more serious damages demonstrating the effectiveness of the traditional techniques in designing and retrofitting masonry buildings (Lucibello et al. 2013).

The structural assessment and retrofitting of important churches in L’Aquila, some of them having a monumental value, has been elaborately studied. Results concerning the seismic behavior of masonry churches have shown that the dynamic excitation due to the seismic ground motion activates many vibration modes of the building structure, though all of them are characterized by small participation factors. Therefore, churches are not behaving through a superposition of global modes but more as dynamic interaction of localized modes. Consequently, in many examined case studies, the ratio between the total base shear and the church total weight ranged between 20 % and 30 %, evidencing a reduction with respect to the plateau value of the spectral acceleration provided by the Italian code. Therefore, appropriate choices of the force reduction factor should be adopted for these monumental buildings different from the case of

traditional residential buildings characterized by shear-type behavior. Further, the activation of many local modes also calls for retrofit interventions, which should “tie up” the building, thus avoiding the local failure modes that are often observed (Brandonisio et al. 2013).

Detailed 3D nonlinear numerical analyses have been performed on several palaces and churches and also on the macroelements composing them such as towers and facades. Linear and nonlinear structural analyses conducted by means of a full 3D finite element model have been used to partially explain the collapse of the transept area of the Basilica of S. Maria di Collemaggio. The transept structural system formed by arches, pendentives, and barrel vaults transferring the vertical loads onto the multilobed pillars has been demonstrated to be vulnerable with respect to both transversal and longitudinal actions. In particular, even in the case of longitudinal actions, the nonlinear static analysis evidences the presence of high tensile stresses in the arches connecting the pillars to the apse walls. This mechanism, observed in the numerical simulations and amplified by the strong vertical acceleration component registered close to the site, together with the minimal resistance of the material inside the core of the collapsed pillars, is the most probable explanation of the implosion of the transept structures in the church (Gattulli et al. 2013).

The bell tower of the San Pietro di Coppito Church in L’Aquila suddenly collapsed during the devastating earthquake, which occurred in April 2009. A series of analyses were performed to provide an ex post evaluation of the causes at the base of the collapse and give operative design information for the reconstruction (Milani et al. 2012). For this aim nonlinear static and limit analysis has been performed evidencing the role played by the actual geometry and by the masonry mechanical characteristics of the tower through reconstructing the failure mechanisms by both modeling approaches. More recently, in a similar modeling approach, an attempt has been made to take into account the effects of fiber reinforcement polymers positioned on a large facade of Palazzo Camponeschi,

as example of engineering analyses on the effectiveness of specific retrofitting intervention with new material on ancient masonry structure in order to augment their seismic capacity (Gattulli et al. 2014).

Finally, the dynamic behavior of masonry structures under three-dimensional shaking is not completely understood, and it needs specific investigations. In this sense, the direct observations and measuring of such behavior through the use of novel structural permanent monitoring systems may help to reach such a goal.

Before the 2009 L'Aquila earthquake, very few structures were equipped by permanent structural monitoring systems managed by the Department of Civil Protection (DPC). However, the response of the Pizzoli Town Hall during the mainshock has been recorded and analyzed by DPC, giving special insights on the potentiality of these systems for immediate evaluation of the damages occurring during an earthquake. Successively, the large amount of installed, temporary or permanent, different types of devices (accelerometers, smart wireless devices, displacement and velocity transducers, inclinometers, etc.) reach a number of around three hundred (300) or more, evidencing a large impact of this technology in the post-earthquake emergency phase, especially during the earthquake swarms (Gattulli 2013). In particular several monitoring systems have been installed in the emergency phase, to understand the occurred behavior in damaged building (Cimellaro et al. 2012; Foti et al. 2013), or during the construction of temporary scaffolding, in order to verify the efficacy of the added structural system especially in the case of monumental building (Russo 2013). Because of this scope, in many cases, the permanent monitoring has worked ranging from a limited number of hours up to several months. In other cases, the monitoring system is permanently installed on the structure for years; it can be used also to determine the change that will occur in the structural behavior during the reconstruction phase (Federici et al. 2012; Gattulli 2013).

In several cases, the structural monitoring system uses only accelerometers, starting from very few measurements to a larger number of devices

with different characteristics and sensitivities. Instead, more complex monitoring systems are used in monumental churches and buildings where accelerometers are accompanied by crackmeters, inclinometers, temperature measurement devices, etc. (Casarin et al. 2012; Russo 2013; Gattulli et al. 2014).

Within this broad range of activities, in the present chapter are summarized specific findings of the researchers of the University of L'Aquila constantly involved to define sustainable reconstruction interventions, in the framework of broad multidisciplinary collaboration, open to the use of innovative technologies and accompanied by valuable training of young scholars.

Seismic Behavior of Ancient Monuments: From Collapse Observation to Permanent Monitoring

The historic center of L'Aquila, which was widely extended before the earthquake, was inhabited by about 7,000 residents and 8,000 students, constituting a large and widespread university campus. In this situation, dense of monuments of great value, characterized by a particular urban fabric, having an orthogonal system due to the Angioina division into lots even if modified by an accelerated stratification, made by previous earthquake, are placed more than 800 businesses, several professional offices, and headquarters of the administrations of various public institutions. This complicated system is developed for about 10 km, including historical centers, consolidated tissues, parts of the city under construction, and the natural park of Gran Sasso and Sirente-Velino. The earthquake has seriously compromised the system and this area corresponds, quite closely, to the so-called seismic crater in which the most important damage occurred. In the revitalization of this large zone affected by the earthquake, a central role is played by the recovery of the L'Aquila historical center accompanied by the similar ones in the neighboring small villages. Hence, the characterization of this system, using a large scale, starting from an urban point of view up to geomorphological and geotechnical vision, is an element of strong relevance also to understand what happens

to the smaller scale of the individual monument, integrating the specific observations with an overview of the problem. Indeed, the numerous campaigns for the characterization of the seismic behavior of the L'Aquila's valley made by a microzoning mesh of the historical center indicated a number of site effects which are very important for better understanding the L'Aquila earthquake and its effects. Recent studies, characterizing the underground of the historical center, point out a sudden transition between the L'Aquila breccia and silty clay loam through a highly detailed reconstruction.

The problem of the reconstruction of historical buildings and monuments, especially within the walls of the historic center, brings to investigate the main open issues concerning the interventions that ensure a real improvement. The structural behavior of the monuments, comprising a masonry structure, still today open to a full understatement, depends on factors such as the mechanical properties of the different materials composing the masonry walls, the features of the horizontal structure and their connection with the vertical ones, and the used construction methods. Therefore, it is important to realize an optimal use of the wealth in the technical and scientific knowledge, stored over the years, to evaluate properly the physical consistency and safety of historical buildings. The answer, of course, cannot be unique but should result in a critical and competent attitude. Some ideas may be received from the reading of a book dealing with the technical problem of preservation. For example, in a classical book on this issue is reported "... In this type of intervention is of particular importance the respect of the typological, structural and functional quality of the system, avoiding those transformations that alter the character." The matter is still very complicated to be solved. Indeed, the properties of fragility, heterogeneity, and anisotropy of masonry and their different typological varieties make it difficult to well describe unitarily their mechanical behavior. Recent technical codes take into account these uncertainties, allowing to use simplified numerical model, implemented "ad hoc," to evaluate the consistency of masonry structures, avoiding the use of

numerical checks that not always ensure a complete reliability. Moreover, the physical nature of masonry structures, product of improvements obtained following successive attempts, and empirical rules lead to the need to examine each case as a special case, making prohibitive to have a general characterization also due to the historic analyses which produces a series of unique cases. However, the entire reconstruction process must also take into account other problems such as energy efficiency, architectural restoration, and refunctionalization. All these actions have to make considering permanent monitoring of the monument so as to better schedule maintenance and following the target of long-term operation of the object.

A series of research groups of the University of L'Aquila have conducted numerous activities related to earthquake engineering immediately after the earthquake to support the city and the entire community strongly hit by the catastrophic event. Here, we attempt to report this huge effort motivated by the willingness to recover as soon as possible to the original state. This entails a path that goes from collapse observation to permanent monitoring, thus characterizing a broadband research activity and picking, according to the authors' opinion, the most significant results. Therefore, the presentation is subdivided in several specific fields.

Collapse and Damage Observation and Survey

A series of partial or complete collapses have occurred in historical buildings at the center of L'Aquila, some of them having monumental value. Among them, one of the most studied is the collapse of the transept of the Basilica di S. Maria di Collemaggio (Gattulli et al. 2013).

The major damage suffered by the Basilica in 2009, indeed, was probably induced by a mechanism of implosion of all the structures that compose the transept: the great multilobed pillars, the triumphal arch and the wall above, the barrel vaults, the dome, and the roofing structures (Fig. 1). In particular, the failure occurred almost simultaneously in the two large pillars and the arches connecting the nave walls with the chancel, closed at the end by the apse, and it was

Seismic Behavior of Ancient Monuments: From Collapse Observation to Permanent Monitoring,

Seismic Behavior of Ancient Monuments: From Collapse Observation to Permanent Monitoring,
Fig. 2 Pillars and columns of S. Maria di Collemaggio:

(a) shaping of the pillars in a multilobed medieval form, (b) material pillar core evidenced by the collapse, and (c) column damages

followed by the overtopping dome collapse. It should be pointed out that the transept is realized through a structural system in which the arch and vault thrusts, induced by permanent vertical loads, play an important stabilizing role. During the simultaneous vertical and horizontal actions of the 2009 earthquake, the equilibrium state in the masonry element was significantly altered. In particular, due to the proximity to the epicenter, the vertical and horizontal acceleration components had similar amplitudes.

Moretti's restoration intervention in the early 1970s was intended to remove the Baroque decorative features added to the Basilica and to unearth the "powerful original structure" of the thirteenth-

century plan, but only the works on the nave had been completed, leaving the transept with its original Baroque decoration. At the same time, he shaped the pillars in a multilobed form, removing material along the height starting from the original multilobed base (Fig. 2). In performing the restoration, the surface of the pillars was realized using blocks of freestone placed around the masonry core of the Baroque pillars having only an aesthetic function with no resistance increase. Small stones placed randomly, and probably coming from previous earthquake debris, were used for the core material.

Moreover, a subhorizontal fracture positioned at the height of around 2 m is present in the north

external wall, hosting the Holy Door, apparently created at the interface between the lower masonry part subjected to grout injection performed during the restoration works conducted in 1999 and the upper masonry part preserving the original workmanship.

Besides that, several of the threaded rods of the bracing system under the central nave roof were broken, almost all in the vicinity of the large crack on the north side wall of the church. In the north aisle, slippage of bolts designed to anchor the wooden trusses was noticed. Both of these cases of damage show the presence of transverse deformations of the longitudinal walls mainly located in the north, which may occur even after the transept collapse.

The damage pattern which affects the columns of the nave walls was developed in a complex manner; there were deep cracks due to heavy compression, initially appearing only in the central columns of the nave (Fig. 2c) and then progressively emerging, with the aftershocks, in almost all the others as well. The progression of damage was very similar to that found during the intervention in the last restoration of the 1970s, which consisted of inserting some missing fragments and grout with cement mortar in the opened joints. The only column that initially exhibited minor damage was the first one towards the transept, which had been completely rebuilt, although simply with brick facing of limited thickness and with an inner core done in small stones immersed in cement mortar.

In all the other columns, large cracks were visible. These columns, in distinction from the first ones, were made using stones shaped like truncated pyramids; these stones were juxtaposed, in an almost dry manner, in order to form the octagonal section. In most cases, cracks occurred in the stone blocks, despite the apparently high resistance of the material. The area of the apse was also characterized by severe damage. This area was affected by clear cracking in the mortar joints of the hewn stone blocks of the main apse, where there were also expelled blocks forming a wedge shape above the mullioned window. Observation of the interior reveals cracks in the apse vault, which is one of the most loaded

elements, a partial detachment, and the presence of permanent relative displacements, which occurred in one of the ribs. The lateral chapels suffered more serious damage. However, the study of the mechanical behavior of the monument cannot avoid to consider the low quality of the masonry, even present in peculiar elements as arches and vaults, exposed clearly in evidence by the collapse (Fig. 3a) and the peculiar realization of the masonry walls at L'Aquila that along the time due to the occurrence of several earthquakes is the product of different craftsmanship (Fig. 3b).

Laser Scanning Measurements

Besides the evident collapses easily visible, the relief of the damage, caused by the earthquake on April 6, 2009, has produced continuous and stimulating activities in damage observation and survey, producing a positive and critical approach about different aspects of the problem. Indeed, in particular regarding this specific area, the catastrophic event was an opportunity to apply the most advanced available technologies in the field. For the first time, the laser scanner technique was extensively used for the surveying of a great portion of L'Aquila territory and in particular for the historical buildings and monuments positioned within the old L'Aquila walls. The survey of the portion of the city hit by an earthquake has been considered, in several cases, a useful support for other structural analysis and conservation and restoration studies. Laser scanning has been used just after the earthquake in L'Aquila and during several summer schools that took place every year since the earthquake, to survey the facades of numerous buildings. The point cloud has been treated and filtered, in order to quantify and verify exactly the deformations due to the earthquake, compared with the original shape and geometry of the building. Laser scanning surveys allow the acquisition of the shape complexity of the building, with its irregularity, not only in some essential lines, as it is in topography. The whole information package is more complex than what is obtained with traditional techniques (topography and photogrammetry), but it is extremely useful for survey and measurements

Seismic Behavior of Ancient Monuments: From Collapse Observation to Permanent Monitoring, Fig. 3 Masonry features at L'Aquila: (a) masonry quality

evidenced by the collapse and (b) masonry walls realized with material belonging to different periods and with different craftsmanship

of structural deformations and cracking. Moreover, the data acquisition system permits to acquire information on difficult geometry from a certain distance, avoiding difficulties related to traditional methods of measurement. Moreover, the University of L'Aquila placed important resources in the field, through several labs (CERFIS, CSE, etc.), renewing the technical equipment and using specialist teams, which operate for the geometric and damage relief. Data processing, made by Leica instrumentation (total station HDS2600 and software Leica Cyclone 7.2) and by a scanner velocity max of 1,016,727 point/s and flow rate in the range of ambiguity of 79 m, permits a return of three-dimensional model (see Fig. 4) from which plants, prospects, and sections can be obtained. The opportunity of having this great volume of data has stimulated to develop interactions between different disciplines, and so they constitute a new wealth of information. In particular the detailed reconstruction of crack path in the main facade of historical buildings (like Camponeschi Palace) allowed a verification of the numerical models to reproduce the observed behavior under

the earthquake and to predict the retrofitting improvements (Gattulli et al. 2014).

Applications of Infrared Thermography for the Investigation of Historic Structures

Infrared thermography is used as a nondestructive technique to identify the most significant inhomogeneity of materials and properties in the surface and structures that are difficult to appreciate by simple visual inspection but are instead detectable by the relief of anomalies associated to thermal phenomena. A portable instrumentation, which consists in thermal imagers, enables the observation of the materials constituting the main and secondary walls (e.g., infill, detachments, fills, and so on) and naturally the discontinuities. The infrared thermography is a noninvasive technique that uses infrared energy emitted spontaneously by any body or object: electromagnetic radiation whose wavelength depends on the temperature of the same body (Wien's law). Because the temperature of the bodies in ambient condition have a wavelength that belongs to the range of infrared spectrum ($\lambda = 0.3 \div 0.78 \mu\text{m}$), the technique is called

Seismic Behavior of Ancient Monuments: From Collapse Observation to Permanent Monitoring, Fig. 4 Reconstruction of tridimensional geometrical models of the structures damaged by the earthquake

using laser scanner techniques: (a) Margherita Palace, headquarter of L'Aquila Municipality, and (b) De Amicis school building

infrared thermography. The value of radiant energy issued change when the objective of the camera passes from a point at a higher temperature to one with a lower temperature, and so also the wavelength of the radiation assumes two different values (Boltzmann's law). Where there is a thermal gradient, the scanner captures the energy variation that is linked with the body temperature through Stefan's law, and so it can determinate the value of emissivity's coefficient. Using a dedicated scanner optical system that investigates point by point all the recorded fields, the camera reproduces an electrical signal representative of the image's thermal information and proportional to its intensity, which will be shown in a kine-scope. In particular for each range of temperature variation, there will be a corresponding range of radiant intensity variation to which the instrument assigns a particular shade of color. The main characteristics of the instrumentation used are the following: minimum focusing distance, 0.3 m; temperature range, from -20°C to $+120^{\circ}\text{C}$; field of view (FOV), $24^{\circ} \times 18^{\circ}$; thermal sensitivity (NETD mK), $<40\text{ mK @ }+30^{\circ}\text{C}$ ($+86^{\circ}\text{F}$); accuracy, $\pm 1^{\circ}\text{C}$ o $\pm 1\%$ of readings;

resolution IR, 640×480 pixel; and spectral field, from 7.5 to 13 m. An extensive campaign of infrared thermography has been conducted to characterize the masonry of Camponeschi Palace, where the Letter and Philosophy Faculty is located. Figure 5 shows a series of findings. Moreover, this technique can be used without any interruption of the current activities and works. The fast data processing allows for the recognition of peculiar masonry zones with doors or windows under the plaster that are partially or completely closed, as well as with the presence of chimneys and underground utilities, masonry wall textures, warping of the floor, nonhomogeneity of the materials, structural damages, delamination of plaster as well as malfunctions of electrical and plumbing systems, infiltration of moisture, leaks, and thermal bridges.

Ultrasonic Testing

In ultrasonic testing (UT), very short ultrasonic pulse waves with center frequencies ranging from 0.1 to 15 MHz and occasionally up to 50 MHz are transmitted into materials to detect internal flaws

Seismic Behavior of Ancient Monuments: From Collapse Observation to Permanent Monitoring, Fig. 5 Infrared thermography results obtained in Camponeschi Palace at L'Aquila: (a) evidence of opening closed with arched lintel, (b) failure of pipes, (c)

identification of concrete elements, (d–g) reading of textures walls under plaster, (h, i) reading of weaving arched lintels, (l, m) presence of openings in the internal masonry walls transversal to the perimeter walls

or to characterize materials. An ultrasound transducer connected to a diagnostic machine is passed over the object being inspected.

There are two methods of receiving the ultrasound waveform: reflection and attenuation. In reflection (or pulse-echo) mode, the transducer produces and receives pulsed waves when the “sound” is reflected back to the device. Reflected ultrasound comes from an interface, such as the back wall of the object or from an imperfection within the object. The diagnostic machine displays these results in the form of a signal with amplitudes representing the intensity of the reflection and the distance and registering the arrival time of the reflection. In attenuation (or through-transmission) mode, a transmitter sends ultrasound through one surface, and a separate receiver detects the transmitted signal on another surface after traveling through the

medium. Imperfections or other conditions in the space between the transmitter and receiver reduce the amount of sound transmitted, thus revealing their presence.

Ultrasonic testing, used on masonry, permits to obtain information about the homogeneity and composition of the masonry wall of the analyzed building. This technique has the benefit to be a nondestructive test and can be done in a very rapid and simple way in wide region of structural parts, but on the contrary, this large volume of data needs a specific interpretation. For this reason, it is important to combine the sonic tests with destructive ones, performed in a limited and significant structural zone, to have a well-specific and useful reference which defines the right relation between the speed of sound and the mechanical characteristics of the investigated masonry. Therefore, it is useful to highlight the main

technical properties of the instrumentation used in a lot of campaign tests at L'Aquila by the University:

- Acquisition, measuring range from 100 mv to 20 v
- Time bases from 20 ns to 81.9 s
- Sample resolution 8 bit
- Samples for event 8,192 for contact measurements, 640 for log, bandwidth 50 mhz, filter for ultrasounds: central frequency 50 kHz, measurement channel 1
- Probes through contact and sonic test with hammer: resonant frequency 53 kHz, diameter

48 mm, maximum frequency for pulse emission: 1 per second, minimum measurement pitch: 10 mm

In Fig. 3 images obtained from sonic tests are reported. From the comparison of the graphs reported in Fig. 3a, b, the distribution of pulse wave speed in the same portion of masonry before and after fluid mortar injection grouting is highlighted. In the first case the maximum speed is 250 m/s, while in the second case it grows up to 1,709 m/s. The different velocity transmission indicates clearly the increase of stiffness due to the grouting (Fig. 6).

Georadar (Ground Penetrating Radar: GPR) Tests

The GPR methodology that employs electromagnetic waves permits the boundary definition of mechanical characteristics of the investigated body by the identification of the interface between layers that have different resistivity and dielectric constant. Structural degradation is classified (four classes of QRI “Quality Radar Index”) by a qualitative analysis of the power radar signal behavior with the depth by both radar anomalies in the section (presence/absence, point 0 and 1) and energy recovery, intense and localized (also called “pick”) in the graphs (point 1 for the pick up to 6 dB, 2 point up to 12 dB, and 3 point over 13 dB). The total QRI is the sum of the two scores described above. The method is calibrated using correlation between radar data and a direct destructive test made on hundred scans acquired on masonry tester. This method permits a direct or relative classification depending on whether there are direct data on each structure or not. The relative classification is divided in four classes: QRI 4, class of low quality; QRI 3, class of medium-low quality; QRI 2, class of medium quality; and QRI 1, class of medium-high quality. In Table 1 the main results of the georadar tests are reported and the obtained classification, in particular, is highlighted in the last column.

In Fig. 7a a grid in the scanned surface of a portion of a masonry wall of the Camponeschi Palace is presented while the obtained results through the georadar test are described in

Fig. 7b in terms of QRI distribution, evidencing a relevant variability of QRI ranging from 1 to 3.25.

Removal of Plaster and Endoscopic Tests

Among minimal invasive tests, the removal of plaster rendered a zone of inhomogeneity, eventually pointed out by infrared thermography, visibly permitting to check the true nature of the walls and of the composing elements. Successively, endoscopic tests have been usually made in several historical masonry walls at L’Aquila. Endoscopy is simply an extension of the essential visual survey into areas inaccessible to the naked eye. The equipment ranges from relatively simple borescopes, consisting of a light source, a small-diameter rigid tube with built-in optics, and an eyepiece, to complex controllable systems with numerous specialized attachments. By drilling a hole (normally less than 12 mm) and inserting the tube, it is possible to inspect voids under floors or behind paneling, for example. Any hidden problems such as fungal growth can, in theory, be identified. The more sophisticated and expensive equipment is fully flexible and can be steered by wires built into the casing. Systems are available down to 6 mm in diameter, and more specialized systems may reach less than 2 mm. It is possible to attach still or video cameras to the eyepiece to record the findings. The theory is fairly simple, but in practice it can be very difficult to retain a sense of scale of the observed image and keep track of the location and orientation of the tip. The focal range, depth of field, and strength of

light are greatly reduced in the smaller diameter systems. It is not unknown for insulation lagging to be misidentified as dry-rot. However, reliable reconstruction of the stratification in the main masonry walls has been obtained, to know the construction technique and to assess qualitatively the physical conditions. The employed instrumentation has permitted to register short movies of what is visible inside the cavities, producing a large quantity of data in digital form to be processed.

Flat-Jack Tests

Several tests of single and double flat jacks were carried in different historic buildings in the center of L'Aquila including Camponeschi Palace, De Amicis school, the headquarter of the Carispaq Bank and Margherita Palace, and others. Moreover, diagonal tests have also been performed to characterize the shear strength in selected masonry panel individuated in existing walls in order to characterize the mechanical properties of the main typology of historical masonry walls at L'Aquila. A probabilistic characterization of the available data on the mechanical features of the historical masonry at L'Aquila is going on in order to have the possibility to investigate the structural assessment of historical buildings,

taking into account explicitly the inherent uncertainties of the problem. A more reliable description of the seismic behavior of the masonry mechanical characteristic will realize a well-balanced design of retrofitting interventions.

Figure 8 summarizes the results obtained through double flat-jack tests realized at different locations of the Camponeschi Palace. The three performed tests evidence the variability in both elastic modulus and measured strength through the adopted testing procedure. Indeed, in the analyzed case, the average strength value is 2.47 N/mm^2 , while the variance is 0.736 N/mm^2 , evidencing the large scatter in the material properties belonging to the same historical building.

Computational Mechanics and Masonry Structural Modeling

Structural analysis and numerical modeling of the seismic behavior of masonry structures is still an open research topic, especially in Italy and in particular after the L'Aquila earthquake. Relevant issues pertain to the inherent uncertainties related to the evaluation of the seismic adequacy of complex masonry buildings through reliable numerical models. Starting from the limit analysis in which the simplified assumption of describing the incipient collapse behavior through chains

Seismic Behavior of Ancient Monuments: From Collapse Observation to Permanent Monitoring, Fig. 8 Results of double flat-jack tests on Camponeschi Palace

Seismic Behavior of Ancient Monuments: From Collapse Observation to Permanent Monitoring, Fig. 9 Principal stresses due to static loads in the

transept: model A, (a) maximum P1 and (b) minimum P3; model B, (c) maximum P1 and (d) minimum P3

of rigid masonry blocks, a series of different modeling approaches have been experimented within the activities of the computational Mechanics Lab of the University of L'Aquila directed by the first author. On this respect, the experience gained at L'Aquila benefits from the large amount of data available for possible comparison with the numerical simulations. Therefore, potentiality and drawbacks of several modeling assumptions have been evidenced along the path, which have shown to be particularly useful also to enrich the tools for retrofitting design. The structural modeling of the Basilica of S. Maria di Collemaggio constitutes a relevant case study in this field. Figure 9 reports, synthetically, the results of two stress analyses induced by live loads conducted by means of two different finite element models of the entire Basilica: in the first case (model A), four-node quadrilateral isoparametric plate-shell elements have been

used to model the main walls in which a prevalent bidimensional behavior has been recognized (Fig. 9a, b) (see also Gattulli et al. 2013); in a second case (model B), a more refined model has been considered in which all the masonry elements have been modeled using eight-node isoparametric solid elements (Fig. 9c, d). It is evident as the stress flux is more clearly defined in the arches and in the pillars by the more refined model, even if the level of stress amplitude is comparable in the two cases. At the same time, the analysis evidences that in the pillars is present an important flexural deformation induced by the thrust differences in the longitudinal direction between the last arch belonging to the nave walls and the arch of the transept on which is laying the dome and the vault. Even if the results are obtained under the hypothesis of modeling the masonry material as an elastic and homogeneous solid, they evidence the role played by the

three-dimensional geometry and the consequent internal action distribution. Figure 9c evidences as the maximum tension flux in the column is prevalently radial, while the minimum one in Fig. 9d is vertical.

A different activity has been carried out on the Camponeschi Palace which represents a good example of how damage observation and experimental survey, performed using the techniques described above, can be a valuable aid in supporting the modeling choices for both damage interpretation and simulating the effect of retrofitting interventions.

The Camponeschi Palace is an important historical building located in the historical city center of L'Aquila. The palace was built near the end of the sixteenth century by the Jesuit order that established and hosted in the structure an institution of higher education. Several modifications to the original configuration and structural interventions have been made during the years. The palace sets upon a rather sloping site and it is characterized by an L-shaped plan with two arms of equal length delimiting an internal courtyard. The building was hosting the Faculty of Philosophy and Letters of University of L'Aquila at the time of the 2009 earthquake.

Due to the relevant structural damage, which occurred, the Department of Civil Protection classified the palace structurally unsafe. The crack pattern of the facade due to the 2009 L'Aquila mainshock and successive earthquake swarms was detected through automated laser-based surveys. The crack pattern distribution of the main facade is shown in Fig. 10a. The major damage was concentrated on the first story. On the left side of the facade, subvertical and diagonal cracks developed at the end sections of the spandrels above and below the openings.

Single and double flat-jack tests were carried out on site in order to evaluate the compressive strength and the deformability properties of the masonry for the entire building.

A numerical model was built specifically to simulate the nonlinear static behavior of the facade and of a retrofitting system using fiber reinforcement polymers for the masonry panels. Eight-node isoparametric plane stress elements

with a 3×3 Gauss integration scheme were used. Figure 10b shows the adopted mesh. The incremental/iterative solution procedure employed is a modified Newton–Raphson approach. A constitutive law, comprising a parabolic hardening rule and a parabolic exponential softening branch, modeled the compression behavior of the masonry; a linear hardening branch followed by a linear softening branch characterized the tension behavior. The FRP reinforcement was modeled using truss elements directly connected to the nodes of the mesh of the panels without using interface elements. Thus, perfect adhesion between the nodes of trusses and the corresponding nodes of the mesh was considered. The strips were considered not able to carry compression loads. The tensile behavior of the FRP was represented with a stress–strain relationship, characterized by a linear elastic behavior in tension, followed by exponential degradation.

Nonlinear incremental static (pushover) analyses were carried out on unreinforced and reinforced facade, separately for the positive (Fig. 10c) and negative x direction (the horizontal one) (Fig. 10d) and for both the unreinforced and FRP-reinforced masonry (Gattulli et al. 2014).

In general, a correct and reliable implementation of the model allows performing in-depth analyses of the expected structural behavior under seismic loads enabling robust design choices.

Structural Monitoring for Historic Structures

Structural health monitoring is an emerging tool for reliable structural assessment. Efficient monitoring programs may help in the characterization of the progressive decay of structural performance, both in the short and in the long term, providing useful information for optimized maintenance and safety. Generally, electronic equipment deployed with the purpose of structural health monitoring is implemented via wired systems. In this case, the development of the system can be limited by a series of factors such as the high cost of measurement equipment, difficulty in installation due to large instruments size, and need of a wired communication and power infrastructure. In recent years, great attention has been

Seismic Behavior of Ancient Monuments: From Collapse Observation to Permanent Monitoring, Fig. 10 Camponeschi Palace: (a) damage pattern on the facade (b) mesh of the FEM model with the FRP layout; numerical pushover curves for horizontal loads (c) +x direction and (d) -x direction

paid to the development of wireless sensor networks that are able to overcome several problems linked to the development of the entire layout but evidencing other issues related to the new technology. One of which is connected to the collection and transmission of a great quantity of data. In fact relevant information can be obtained by the registrations of the vibration data induced by ambient sources, wind, earthquakes with low intensity, operation of machines, and traffic. The sensors are placed in specific points of the structure and appropriately selected and the choice of which is based, for example, on numerical modeling. Using the acquired data, it is possible to identify dynamical models, which predict the observed behavior on the basis of error minimization. Differences in the identified systems produced by data acquired in different periods separated by a long interval of time may permit to identify relevant changes in the behavior of the systems which can be linked to degradation of the structural performance or incurred damages. For example, in largely damped, like masonry, structures, it is convenient to use high sampling times for acquisition as opposed to frame structures. Although the interesting structural modes can be placed within an interval 0–10 Hz, the structural response may be highly damped and attenuated with a reasonable amplitude level contained in few seconds. The acquired time histories under seismic action will be composed of a few samples that make difficult the reconstruction of the frequency spectrum. Some important benefits are that smart sensors include microprocessors that are able to run some basic algorithmic tasks and then store some condensed information to be exchanged between the other sensors (nodes) that comprise the wireless network (WN).

The long-term activity at the University of L'Aquila aims to develop innovative automated techniques, which permit to automatically update the appropriately selected models, which in turn may address questions regarding the seismic safety of the monitored structures. In particular, following a parametric identification approach, using the distributed available measurements from sensors embedded in the

reinforcements, the mechanical parameters characterizing the local behavior of the reinforcement either in the reinforcing fibers and in their support may be opportunely monitored. Subsequently, through information data fusion made available by arrays of sensitized reinforcements distributed on a masonry macroelement, mechanical parameters influencing the global behavior may be identified. Possible developments concern the use of measurements at different levels of excitation amplitudes, which are available in seismic areas. They may be used to define a methodology for identifying nonlinear behavior, distinguishing between scenarios where damage occurs in the fiber, in the support, or in the masonry structure.

The implementation of a full SHM system in historical buildings is still an open problem especially in aspects relating to the correct fusion of vibration measurements, integrated with other type of measurements. For example, in concrete structures it has proven useful to follow the trend of humidity and temperature in order to evaluate deterioration and updated material performances. In this manner early assessment and warning of incipient problems may be used to drive quick interventions or the planning and scheduling of the maintenance programs. To the contrary, in monumental structures often numerous cracks are present which can be the objective of permanent static monitoring. Indeed, following the slow opening and closing of the crack may be used as an important correlation measurement for validating information provided for the identification of other parameters. The opening and closing may depend on the cyclic trend of the average temperature corresponding to a certain time interval (day, month, season). Similarly to this trend, it may possible to observe a reduction or increase of stiffness or a change of configuration that may induce also a cyclic trend in the identification of natural frequencies.

Of course, this set of actions permits both a rationalization of the cost and an improvement of the service-life predictions, potentially also for monumental structures, especially if they have been recently restored and retrofitted with a consequent important investment.

In general there are no particular rules for the design of a fully operating SHM system, but each case is unique and it requires particular care especially with respect to the goals to be achieved. The observation and the investigation on the damage reported by the structure after a seismic event can lead to a customized system able to provide specific information for continuously assessing structural condition. Correlations among obtained results should be sought for and only after analyzing all available information; the responsible team, formed by professionals with different skills (structural, geotechnical, architectural, electronic, and informatics), on the basis of their experience and sensibility, can formulate a final diagnosis and define the actions to be performed.

Within such a context, in the first phase of the SHM system deployment, at the Basilica di Santa Maria di Collemaggio, different actions have been performed including design, implementation, installation, and test of a network monitoring accelerations. The main goal was an accurate measurement of the basic structural response, both to environmental actions and to low-amplitude seismic events, which occasionally continue to occur at the site. A wireless sensor network was used as a platform combining a MEMS tri-axial accelerometer and also sensors to measure humidity, temperature, and luminosity (Gattulli et al. 2014). The proper positioning of the sensors has been designed through the study of different numerical models accounting for the interaction between the main wall element and the temporary scaffolding (Fig. 11a). In particular, the dynamic behavior can be observed looking at the principal modal characteristics (frequency, modal shape, and percentage of participating mass) of the linear dynamic response (Fig. 11b, c). The analyses suggest, for example, that, by placing the sensors along the internal longitudinal facade, it is possible to survey the transversal displacements especially during a seismic event. Until today, after almost 3 years of permanent monitoring, the system is still able to capture relevant data during the occurrence of several seismic events coming from far and near fields. Generally, the registered maximum

response amplitude in the acquired time history (one of this shown in Fig. 11f) determines the possibility to get information regarding the main modal features.

Nowadays, in order to derive the processed information, from experimental data, different modal identification procedures can be used which are generally classified based on whether they operate in the time domain or in the frequency domain. However, the amount of contained information is relatively independent of the analysis domain.

Among several procedures probably, the two most popular algorithms are the Enhanced Frequency Domain Decomposition (EFDD) and the Stochastic Subspace Identification (SSI) (Peeters and De Roeck 2001), and the first operates in the frequency domain and the second in the time domain.

The two procedures assume that the system input (loads) is white noise that can be thought as a representative model of environmental noise. However, even if the adoption of the white noise model in the case of a seismic event may be questionable, the straightforward applications of the abovementioned procedures to response data acquired during small earthquake still allow to derive valuable information especially if special care is taken, such as in the case of the studied system at the Basilica (Gattulli et al. 2015a, b). Indeed, here, using the SSI procedure, for example, the evaluation of the identified stable poles may include dominant components of the input, producing possible errors or misinterpretation of the dynamic behavior. However, the direct comparison with results obtained by numerical models driven by engineering judgment permits to extract realistic structural modal data. Moreover, the robustness of this data can be pursued through the use of several different registrations generated by earthquakes with different characteristics dependent on the source location. Following the reliable identification of the modal characteristics, the second step is the updating of the numerical model parameters in order to minimize the error between measured and numerical modal features. In the error index formulation, natural frequencies and/or modal shapes

(a) stabilization diagram of the SSI procedure; (b) first (0.90 Hz) and (c) second (1.45 Hz) identified mode shape

may be considered. In the first case, a simple difference in percentage is generally considered, while the Modal Assurance Criteria (MAC) is used to compare measured and numerical modal shapes. The MAC criterion indicator permits to evaluate the differences between similar modes but also the cross-orthogonality between different numerical and experimental modal shapes. As an example, Fig. 12a illustrates the stabilization diagram obtained from the time histories acquired by the wireless sensor network using SSI during a seismic event. The ordinates include the model order, which simply refer to the size of

the Hankel matrix considered in the identification process, while the abscissa is reporting the frequency; the circles with a cross inside indicate stable modes, while the others, colored in gray, are unstable. At least one stable mode is present at different frequencies, but in the case of two specific frequencies, stable modes seem to be present at almost all different model orders considered in the analysis. These stable poles are present at 0.90 Hz and in the range between 1.45 and 2 Hz. In the latter case, a comparison with numerical models permits possible interpretation of the modal identification. The first two

identified modes are illustrated in Fig. 12b, c illustrating the deformed shape of the portion of the Basilica in which the response used in the identification procedure has been registered. The second phase of the monitoring system development involves the deployment of crackmeter and inclinometer sensors at the Basilica. Figure 11d summarizes the employed instrumentation, where the red circles indicate the wireless sensor network relative to the accelerometer; the blue squares and the orange triangles correspond to the crackmeters and the inclinometers, respectively. Moreover, the green circles refer to an accelerometer placed at the base of a pillar necessary for acquiring the acceleration of the seismic input, while the star indicates the positioning of the node gateway that collects the data of each sensor and sends them to the server. The data fusion of the two sets of information is currently under investigation.

Summary

The earthquake, which occurred on April 6, 2009, has been a catastrophic event for both the city and the University of L'Aquila. Nevertheless, the disaster has transformed itself into a tremendous opportunity to revitalize the area, providing the potential for the national and international scientific community to test the effectiveness of new systems and technologies and consequently to establish main directives for the monitoring of monumental structures. The applicability of new technologies in the areas of observation, surveying, testing, modeling, restoration, retrofitting, and monitoring of ancient monuments, of which the city center is densely populated, is extensively documented herein, through an organized outline and a series of case studies.

Introduction

In earthquake engineering, structural collapse is defined as the local or global failure of a system that occurs due to the loss of vertical load-carrying capacity in the presence of seismic events. The two primary modes of global collapse are sidesway and vertical collapse. Sidesway collapse is the global failure of the system caused by a reduction of the lateral load-bearing capacity due to large horizontal displacements, whereas vertical collapse is caused by a direct loss of the gravity load-bearing capacity in one or several structural components (Krawinkler et al. 2009). Vertical collapse is a type of progressive collapse, which is the total or disproportionate failure of the system triggered by an initial local failure that spreads out from element to element.

Commonly, in ductile frame structures, sidesway collapse is the predominant mode of

collapse during catastrophic earthquake events. These systems are affected by component material deterioration and/or P-delta effects. Material deterioration reduces the component's strength under large inelastic displacements. Moreover, the strength and stiffness of the structural components deteriorates in each load cycle, reducing the load-bearing capacity. The importance of material deterioration decreases for long-period structures, where the P-delta effects (also referred to as second-order effects) may lead to a negative post-yield stiffness that in combination with large inelastic displacements accelerates the onset of collapse.

In most non-ductile frames, however, columns lose the capacity to sustain gravity loads due to shear and subsequent axial-load failures, and as a result, the collapse mechanism is controlled by the loss in vertical load-bearing capacity. As outlined in Baradaran Shoraka (2013), this type of collapse of older concrete buildings may be precipitated by axial-load failure of columns, punching shear failure of slab-column connections, failure of slab-diaphragm connections, or axial-load failure beam/column joints.

Prediction of earthquake-induced collapse requires the identification of all possible modes of collapse, appropriate structural modeling of building components under cyclic loading, and suitable representation of earthquake excitation including the consideration of epistemic and aleatory uncertainties. Krawinkler et al. (2009), Haselton et al. (2009), and Baradaran Shoraka (2013) provide insights into the phenomenon of dynamic collapse of earthquake-excited structures. For basic concepts in prediction of collapse and its implementation to performance-based earthquake engineering, the reader is referred to Zareian et al. (2010). Villaverde (2007) presents a comprehensive literature that provides a path through which seismic collapse assessment has evolved in the last decades.

The required accuracy and the available resources determine the selection of a seismic collapse assessment procedure. In a first step, the governing seismic modes of collapse such as vertical collapse or sidesway collapse are identified. Then a structural model is created that

Seismic Collapse Assessment, Fig. 1 Force-displacement relations from a monotonic and a cyclic test (Modified from Gatto and Uang 2002; With permission from Prof. Uang, UC San Diego)

captures these failure modes, and modeling uncertainties are quantified. Evaluation of seismic collapse should be based on structural analyses that incorporate strength and stiffness material deterioration, as well as geometric nonlinearities (P-delta effects). Collapse of single-degree-of-freedom (SDOF) systems was first studied by including only P-delta effects in seismic response, which may cause a negative inelastic tangent stiffness that eventually leads to system collapse (Jennings and Husid 1968; Bernal 1987; MacRae 1994). The development of hysteretic models that include strength and stiffness deterioration (Kunnath et al. 1990; Sivaselvan and Reinhorn 2000; Song and Pincheira 2000; Ibarra and Krawinkler 2005) improved the assessment of collapse capacity. As observed in Fig. 1, collapse assessment requires models that can predict strength reduction under large displacements, as well as strength and stiffness deterioration due to cyclic loading.

This article focuses on sidesway collapse of frames, which has been traditionally estimated by means of non-degrading systems, in which judgmental limits are assigned to response quantities such as roof drift, story drift, ductility, and hysteretic energy. These parameters are usually referred to as engineering demand parameters (EDPs) (Moehle and Deierlein 2004). The development of degrading models permits tracking the collapse limit state, but EDPs become very sensitive when the system is close to collapse, and

Seismic Collapse Assessment, Fig. 2 IDA curve for a single ground motion up to collapse: elastic, inelastic, and EDP-sensitive domain; collapse (With permission from Adam 2014)

small perturbations in input parameters lead to large variations in the response. For this reason, global collapse methodologies are commonly based on an intensity measure (IM) instead of an EDP. A relative IM is the ratio of ground motion intensity (demand) to a structure strength parameter (capacity). For a given structure and ground motion, collapse evaluation consists of a series of response history analysis starting with a relative intensity that produces an elastic response of the system. Then the relative intensity is increased to cover the full range of interest or until collapse takes place. This series of response history analysis is called incremental dynamic analysis (IDA) (Vamvatsikos and Cornell 2002). As an example, Fig. 2 shows an IDA curve that results from increasing the IM up to collapse. Collapse is imminent when a very small increment in relative intensity causes a very large increment in the EDP of the system, a condition that indicates dynamic instability. In Fig. 2 dynamic instability occurs when the slope of the IDA curve approaches zero.

The global seismic collapse capacity of a system is defined as the largest earthquake intensity at which the structure still maintains dynamic stability (Krawinkler et al. 2009), denoted as CC in Fig. 2. This definition is associated with a specific structure under a given ground motion. Dynamic analysis requires the specification of system properties and input ground motions, but variations in these quantities may produce large dispersion in the response. Therefore, collapse

needs to be evaluated in a probabilistic framework that includes uncertainties in the frequency content of the ground motions (e.g., record-to-record (RTR) variability) and in the input parameters of the system (e.g., epistemic uncertainty). Then, nonlinear response history analyses usually include a set of ground motion records that represents the RTR variability at the site of the structure. The effect of uncertainty in nonlinear deterioration parameters on the variance of collapse capacity can be quantified by means of approximate methods (e.g., FOSM method) or carrying out Monte Carlo simulations (Ibarra and Krawinkler 2011; Ugurhan et al. 2014).

The variance in collapse capacity can be used to generate collapse fragility functions that provide the probability of collapse given that an event with a certain IM occurred. Shome and Cornell (1999) summarize the arguments used to consider the collapse fragility as a log-normally distributed function. For simplified procedures, only the median, 16th, and 84th percentiles of the individual collapse capacities are required to find an approximation of the collapse fragility. A final product of collapse assessment is the mean annual frequency of collapse, which is obtained by combining fragility curves with the hazard information at the site.

In this contribution some of the issues involved in seismic sidesway collapse assessment of moment-resisting frames are addressed in more detail, including nonlinear dynamic analysis, structural modeling, strength and stiffness

material deterioration, and P-delta effect. The probabilistic framework used to evaluate collapse and the effect of epistemic uncertainties and aleatory variability on the collapse capacity variance are discussed, although ground motion selection is not part of this article. The last sections deal with the development of simplified methods to evaluate collapse capacity.

Nonlinear Dynamic Analysis

In the last two decades, significant progress has been achieved in the nonlinear dynamic analysis of structures. It is now established as the most reliable tool to predict realistically the seismic collapse capacity of a building, and several provisions such as FEMA P-695 (2009), ATC-58 (2012), and ATC-78 (2013) propose collapse assessment methodologies based on nonlinear dynamic analysis.

Incremental Dynamic Analysis

If sidesway collapse is the governing failure mechanism, the IDA procedure can be used to determine the largest earthquake intensity at which the structure still maintains stability. In this approach nonlinear dynamic response history analyses are performed repeatedly, increasing in each subsequent run the ground motion intensity. The IDA curve of the structure for the considered earthquake record is obtained by plotting an appropriate record intensity measure against its corresponding EDP (Vamvatsikos and Cornell 2002). The analysis can be stopped when the EDP satisfies a certain failure criterion that may correspond to structural sidesway collapse. In this case, the corresponding intensity of the ground motion is referred to as collapse capacity of the building for this specific ground motion record.

IDA is commonly performed for a representative set of ground motions to account for RTR variability. Examples of such sets are the LMSR ground motions (Medina and Krawinkler 2003) and FEMA P-695 sets for far-field and near-field ground motions (FEMA P-695 2009). In this sense, the ground motions are used as standardized excitation protocols, and the effort of

selecting ground motions is avoided (Baker 2013). These records need to be scaled to the same IM, and since there is not a unique definition, several IMs have been proposed: (a) elastic ground motion-based scalar IMs such as peak ground acceleration (PGA), peak ground velocity (PGV), and peak ground displacement (PGD); (b) elastic and inelastic spectral-based IMs such as spectral acceleration and spectral displacement at the fundamental period of the structure, as well as spectral values related to higher mode effects or period elongation; and (c) vector valued IMs (e.g., Baker and Cornell 2005). Currently, the most widely used IM is the 5 % damped spectral pseudo-acceleration $S_a(T_1, \zeta = 0.05)$ at the fundamental period T_1 of the structure. For example, if $S_a(T_1, \zeta = 0.05)$ is normalized by the product of the acceleration of gravity g and the base shear coefficient γ , the relative seismic collapse capacity of the building subjected to the ground motion “ i ” reads as

$$CC_i = \frac{S_{a,i}}{g\gamma} \Big|_{\text{collapse}} \quad (1)$$

The base shear coefficient γ is defined as the base shear V_y at onset of yielding divided by the total weight W .

The collapse fragility function is obtained by counting the fraction of collapse capacities CC_i ($i = 1, 2, \dots, n$) that correspond to the n ground motions of the considered set. When all ground motions lead to collapse, the collapse capacity distribution is usually log-normal distributed (Ibarra and Krawinkler 2005). As an example, Fig. 3 shows the IDA curves of a structure subjected to the 44 ground motions of the FEMA P-695 far-field ground motion suite and the corresponding collapse fragility function.

Multiple Stripe Analysis

The IDA approach cannot consider certain site-specific ground motion conditions. As outlined by Baker (2013), some of the ground motion properties relevant for collapse assessment are the spectral shape of the elastic response spectrum, the duration, and the effects of near-fault ground motions and velocity pulses. The

Seismic Collapse Assessment, Fig. 3 (a) IDA curves of a structure for all records of a ground motion set. (b) Counted collapse fragility and corresponding fitted

fragility function according to a log-normal distribution (With permission from Adam 2014)

expected spectral shape of a ground motion does not only vary with location but it also depends strongly on the ground motion amplitude (Baker and Cornell 2006). For instance, at different seismic intensity levels, the spectral shape of the expected earthquake is dissimilar. These differences in the spectral shapes can be ascribed to the soil condition, magnitude, distance, and parameter ε , which quantifies the difference between the selected ground motion's spectral acceleration at a specific period and the median of the ground motion spectral acceleration obtained from attenuation relationships (Baker 2013). Because the same set of records are often used for different locations, however, IDA yields the same risk of sidesway collapse for two equal buildings located in different locations with similar seismic hazard, although the anticipated ground motion spectral shapes are different.

To address some of the above issues, Jalayer and Cornell (2009) developed a multiple stripe analysis (MSA) that accounts for specific site conditions and for ground motion properties that change with increasing magnitude. In this approach, the ground motions are reselected at each IM level according to the changing spectral shape. For each record the peak response of the EDP derived from nonlinear response history analysis and the number of events that leads to sidesway collapse is plotted as a function of the corresponding IM, thus leading to "stripes."

The counted fraction of observed individual collapses at each IM level leads then to the collapse fragility curve.

Collapse Criteria

The numerical sidesway collapse prediction depends on the model capabilities. Historically, the first nonlinear numerical models did not include deteriorating characteristics, and damage indexes were developed to predict collapse based on maximum displacements and/or dissipated energy. The most widespread cumulative damage model was the Park–Ang model (Park and Ang 1985), which was developed specifically for reinforced concrete components. The damage measure (DM) consisted of a linear combination of displacement and energy demands:

$$DM = \frac{\delta_{\max}}{\delta_{\text{ult}}} + \frac{\beta}{F_y \delta_{\text{ult}}} \int dHE \quad (2)$$

where $\delta_{\max}$ is the maximum displacement of the system, δ_{ult} denotes the monotonic displacement capacity of the system, β represents the structural performance parameter, and HE is the hysteretic energy. In concept, the parameters δ_{ult} and β of this cumulative damage model are equivalent to the deteriorating parameters of recent hysteretic models that include cumulative deterioration. However, damage index models were based on non-deteriorating models, leading to unrealistic

Seismic Collapse

Assessment, Fig. 4 Two IDA curves for the same building and ground motion record based on two different structural models. Definition of the collapse capacity: $CC_i^{(u)}$ collapse capacity associated with infinite deformation. $CC_i^{(d)}$, $CC_i^{(n)}$: collapse capacity predictions based on a predefined EDP limit (With permission from Adam 2014)

displacement–force relationships for large inelastic excursions.

In recent practical applications, when non-degrading models are used to predict collapse, this limit state is associated with the deformation of a single structural component that exceeds a predefined EDP threshold, often represented by a plastic rotation demand (Haselton et al. 2009). Eurocode 8 (CEN 2005) provisions, for instance, are based on capacity thresholds for the deformation of RC members at yielding and failure developed by Fardis and collaborators (e.g., Panagiotakos and Fardis 2001; Fardis and Biskinis 2003). As a further example, ASCE/SEI 41-13 (2014) procedure compares the component demands of an existing building with component acceptance criteria that define collapse prevention. In such an approach, the component that fails first governs the state of the entire structure. That is to say, component capacity thresholds do not capture the global behavior and the capability of the structure to redistribute forces after failure of one component.

A structure may exhibit several modes of seismic-induced collapse such as sidesway collapse or vertical collapse, depending on the history of spread of inelastic deformations, load distribution, etc. If the corresponding degrading structural model captures only a specific type of collapse such as sidesway collapse, the other collapse mechanisms that might occur are referred to non-simulated modes of collapse. That is, they only can be predicted by an artificial

criterion such as the exceedance of a predefined EDP threshold. In particular non-ductile collapse modes such as column shear failure and subsequent vertical collapse are frequently considered as non-simulated collapse modes (e.g., Liel and Deierlein 2013).

The IDA curves of Fig. 4 illustrate sidesway collapse prediction for degrading and non-degrading structural models. The intensity $CC_i^{(u)}$ is the ultimate collapse capacity associated with infinite EDP deformations for the degrading model, and it corresponds to the “exact” collapse capacity. However, if a predefined deformation threshold is used to define collapse, the use of the degrading model always results in a conservative near-collapse prediction. That is, the intensity at this EDP threshold, $CC_i^{(d)}$, is smaller than $CC_i^{(u)}$. On the other hand, the use of a non-degrading model may underestimate or overestimate the actual collapse capacity, depending on the preestablished EDP threshold. In Fig. 4 the corresponding intensity denoted as $CC_i^{(n)}$ results in a nonconservative prediction because the predefined EDP threshold is rather large.

Baradaran Shoraka (2013) developed a robust collapse assessment framework to predict vertical collapse, such as column shear failure and subsequent axial failure in non-ductile reinforced concrete frames. In this approach, progression of damage is tracked throughout the numerical analysis by comparing stepwise floor level gravity demands with corresponding capacities. Explicit modeling of progressive collapse involves

element (commonly column) removal until the structure attains a state that cannot resist the vertical load demand. Baradaran Shoraka et al. (2014) also compared the results of explicit gravity load collapse modeling and those obtained from nonlinear acceptance collapse prevention criteria specified in ASCE/SEI 41-13 (2014) for retrofit of non-ductile frames.

Structural Modeling Strategies for Assessing Sidesway Collapse

Structural Modeling on the System Level

The structural model may be two-dimensional or three-dimensional, but when the building exhibits a coupled bending-torsional response, a three-dimensional system better predicts the building seismic behavior. Such a system requires sophisticated modeling of the nonlinear constitutive behavior at the component level that is not well understood. Thus, three-dimensional models are avoided for collapse analysis as long as it is feasible, and a more generic two-dimensional structural model is utilized.

As outlined by Krawinkler et al. (2009), there are two practical modeling strategies for frame structure evaluation: fiber models and lumped plasticity models. In a fiber model, an axial stress–strain relation is separately assigned to each fiber of the cross section. For example, different constitutive laws can be used in reinforced concrete sections to represent confined and unconfined concrete and the longitudinal steel bars. In this manner, the spread of inelastic deformations within the structural component is captured. In many situations this approach can accurately predict earlier limit states such as yielding and crack initiation, among others. However, several problems have been observed in fiber models. Since these models usually are based on axial stress–strain relations, shear deformations cannot be modeled appropriately. According to Krawinkler et al. (2009), further phenomena that are difficult and often impossible to capture are, for example, bond slip, rebar fraction and rebar buckling, fracture of concrete, and local and lateral torsional buckling in steel. Since

these phenomena may govern the deterioration process, strain “artificial” limits need to be specified in fiber models (Krawinkler et al. 2009).

In a lumped plasticity model, locations within the structure that might undergo inelastic deformations in a severe seismic event are identified up front. Inelastic nonlinear zero-length springs are assigned to these locations, while the rest of the model components remain elastic. These simple phenomenological component models are calibrated with experimental outcomes to represent appropriate cyclic response behavior.

For instance, in a moment-resisting frame, rotational springs are placed at the end of beams and columns. Frames are designed according to the strong column-weak beam philosophy, in which beams and bottom end of base columns are intended to exhibit inelastic deformations at their ends when subjected to strong ground motions. However, many columns may undergo inelastic deformations at the story level when approaching the collapse limit state. Thus, nonlinear spring elements need to be placed at these locations to accurately predict the seismic collapse capacity.

A concentrated plasticity model includes beam/column elements of different degree of sophistication. In the simplest case, all elastic, inelastic, and deteriorating properties of the element are assigned to rotational springs at both ends of the element, whereas the element itself is considered to be rigid; see Fig. 5a. This model may capture the development of plastic hinges. As a disadvantage the spring stiffness must be defined a priori, which is a constant regardless of the potential changes in the moment gradient of the element. To avoid this drawback, Ibarra and Krawinkler (2005) suggest to keep the beam/column element elastic and to add rotational springs at the ends, whose rotational stiffness is several times stiffer than the rotational stiffness of the elastic beam/column element. In this model, an elastic beam/column element is connected to two springs at the ends, and thus, the properties of the parameters can be calibrated according to the component “real” behavior (Fig. 5b). Jäger and Adam (2012) showed that the latter element can describe column and beam behavior sufficiently

Seismic Collapse Assessment, Fig. 5 Different beam/column elements and their constitutive behavior to monotonic loading. (a) Rigid element with two nonlinear

rotational springs. (b) Modified elastic element with two nonlinear rotational springs (Modified from Jäger and Adam 2012)

accurate for collapse assessment. The rigid element with two nonlinear springs at its ends should be used for beams only because when it is used in columns, the elastic axial-bending loading interaction cannot be taken into account. A shortcoming of lumped plasticity models is that the nonlinear column spring strength remains constant during the response history analysis, independently of the moment - axial force interaction.

Figure 6a shows a concentrated plasticity model for a multistory three-bay steel moment-resisting frame, whose plan configuration is shown in Fig. 6b. At both ends of each beam and column, a nonlinear rotational spring is arranged with an offset from the node to account for the member's cross section. In contrast, generic frame models used for research purposes are often “centerline models,” i.e., the lumped plasticity elements are located at the nodes without any offset from the nodal point.

The structural model of Fig. 6a includes a leaning column with zero flexural stiffness to account for the P-delta effect resulting from gravity loads that are not directly applied to the frame (Haselton et al. 2009). This leaning column is loaded with a vertical load at each story level representing half of the total system gravity load that is not directly tributary to the columns of the frame (NIST GCR 10-917-8 2010), as shown in Fig. 6b.

Another issue that needs to be properly addressed is modeling of viscous damping for

nonlinear dynamic analysis. Several studies have revealed that inappropriate consideration of viscous damping leads to spurious damping forces that distort the nonlinear dynamic response prediction. Particularly affected are lumped plasticity models with elements that exhibit large initial stiffness (Charney 2008). According to the ATC-72-1 report (ATC-72-1 2010), modal damping is the preferred choice for modeling of damping in inelastic structures, but in many software packages, this is not possible. In such cases a combination of mass and stiffness proportional damping (e.g., Rayleigh damping) should be used. Modeling guidelines for damping in inelastic structures are provided in ATC-72-1 (2010).

Structural Modeling of Cyclic Component Behavior

Sidesway collapse assessment based on lumped plasticity structural models requires hysteretic models that include all the important modes of deterioration observed in experimental tests. As illustrated in Fig. 7, monotonic tests on structural components show that strength of the backbone curve is “capped” and is followed by a negative tangent stiffness. In addition, the cyclic response indicates that strength and stiffness deteriorate with the number and amplitude of cycles. As a result, the strength predicted by the monotonic backbone curve is usually not reached during cyclic loading. Several hysteretic models have been developed to represent this behavior (e.g., Song and Pincheira 2000). However, few models

Seismic Collapse Assessment, Fig. 6 Example of structural modeling of a frame building. (a) Overall lumped plasticity structural model of the moment-

resisting steel frame. (b) Rectangular plane configuration of the frame building (Modified from NIST GCR 10-917-8 [2010](#))

integrate strength deterioration in the backbone curve, as well as cyclic deterioration of strength and stiffness. This section describes exemplarily the deteriorating models developed by Ibarra et al. (2005) for bilinear, peak-oriented, and pinched hysteretic systems.

Figure 8 presents bilinear, peak-oriented, and pinching deteriorating models based on a backbone curve that includes a post-capping negative slope, and sometimes a residual strength, as shown in Fig. 7. The deteriorating models preserve most of the rules of the original non-deteriorating models. For instance, the

bilinear model (Fig. 8a) is based on the standard hysteretic bilinear rules with kinematic strain hardening, but a “strength limit” is introduced when the backbone curve includes a branch with negative slope. The limit for strength is the smallest strength reported on the post-capping branch in previous excursions. If this condition were not established, the strength in the loading path could increase in later stages of deterioration. Note that the original peak-oriented and pinching models exhibit stiffness deterioration in the reloading path. However, in this article the term “deterioration” is used for hysteretic

Seismic Collapse Assessment,

Fig. 7 Initial backbone curve for the modified Ibarra–Krawinkler model (Modified from Krawinkler et al. 2009)

Seismic Collapse Assessment, Fig. 8 Basic deteriorating hysteretic models: (a) bilinear, (b) peak oriented, and (c) pinching (Modified from Ibarra and Krawinkler 2005)

models that possess a post-capping stiffness branch in the backbone curve. These models may also be subjected to cyclic deterioration.

The peak-oriented model (Fig. 8b) keeps the basic hysteretic rules proposed by Clough and Johnston (1966), but the backbone curve is modified to include strength capping and residual strength. The negative post-capping stiffness does not modify any basic rules of the model. The pinching model is similar to the peak-

oriented one, but the reloading consists of two parts. First the reloading path is directed toward a “break point,” which is a function of the maximum permanent deformation and the maximum load experienced in the direction of loading. The break point is defined by the parameter κ_f that modifies the maximum “pinched” strength (points 4 and 8 of Fig. 8c) and the parameter κ_d that defines the displacement of the break point (points 4' and 8').

Component Deterioration Based on Hysteretic Energy Dissipation

Consideration of cyclic component deterioration is important for collapse prediction, especially for short-period highly ductile systems. The Ibarra–Krawinkler hysteretic model includes four cyclic deterioration modes based on energy dissipation that are activated once the yielding point is surpassed. As observed in Fig. 9, basic strength and post-capping strength deterioration effects translate the strain-hardening and post-capping branch toward the origin, unloading stiffness deterioration decreases the unloading stiffness, and reloading (accelerated) stiffness deterioration increases the target maximum displacement.

The amount of deterioration depends on the parameter $\beta_{m,i}$, which is based on the hysteretic energy dissipated when the component is subjected to cyclic loading (Ibarra and Krawinkler 2005),

$$\beta_{m,i} = \left(\frac{E_i}{E_{t,m} - \sum_{j=1}^i E_j} \right)^{c_m} \quad (3)$$

where E_i is the hysteretic energy dissipated in excursion i , $\sum E_j$ represents the hysteretic energy dissipated in all previous positive and

negative excursions, and $E_{t,m}$ denotes the hysteretic energy dissipation capacity for the cyclic deterioration mode “ m .” The original hysteretic rules defined $E_{t,m}$ as a function of twice the elastic strain energy, $E_{t,m} = \gamma_m M_y \varphi_y$ (Ibarra and Krawinkler 2005). The modified Ibarra–Krawinkler model defines $E_{t,m}$ as a function of the plastic chord rotation φ_p , $E_{t,m} = \lambda_m M_y \varphi_p$, or $E_{t,m} = \Lambda_m \varphi_p$ (Lignos and Krawinkler 2012). The parameters γ_m , λ_m , and Λ_m are calibrated from experimental tests, and reasonable results are obtained if all cyclic deterioration parameters have the same value. Exponent c_m is the rate of deterioration parameter. $c_m = 1$ implies a constant rate of deterioration.

The parameter $\beta_{m,i}$ modifies the strength and stiffness properties of the previous cycle. For basic strength deterioration, for instance, the strain-hardening branch moves toward the origin by an amount equivalent to reducing the yield strength as follows (for this mode index $m = s$):

$$M_{y,i}^+ = (1 - \beta_{s,i}) M_{y,i-1}^+ \quad (4)$$

where $M_{y,i}^+$ is the deteriorated yield strength after excursion i and $M_{y,i-1}^+$ is the deteriorated yield strength before excursion i . Except for the unloading stiffness mode, a positive and a negative value is defined for each deterioration parameter because the algorithm deteriorates the strength independently in both directions.

Seismic Collapse

Assessment, Fig. 9 Four modes of component deterioration in a pinching component (Modified from Lignos and Krawinkler 2013; With permission from American Society of Civil Engineers)

Seismic Collapse Assessment,

Fig. 10 Inelastic structural response history with ratcheting effect due to P-delta (With permission from Adam 2014)

That is to say, $M_{y,i}^-$ is updated after every positive inelastic excursion, and $M_{y,i}^+$ is updated after every negative inelastic excursion. For example, $\beta_{s,i}$ is calculated each time the inelastic path crosses the horizontal axis. These parameters are calibrated from experiments. For instance, Lignos and Krawinkler (2012, 2013) conducted deterioration modeling of steel components based on an experimental database.

Global Seismic Sidesway Collapse and the P-Delta Effect

In a vibrating structure, gravity loads acting through large horizontal deflections induce additional bending moments, which in turn increase the lateral deflections. In structural analysis, this destabilizing effect of gravity loads (i.e., global P-delta effect) is usually interpreted as a reduction of the lateral structural stiffness by the so-called geometric stiffness. Generally, for a real building within its elastic range of deformation, this stiffness decrease is of minor importance because its magnitude is small compared to the first-order elastic stiffness. During severe seismic excitations, however, inelastic deformations combined with gravity may cause a structure to approach a state of dynamic instability if the post-yield tangent stiffness becomes negative. In such a condition, the displacement response tends to amplify in a single direction due to the ratcheting effect, as shown in Fig. 10. Very flexible structures are especially affected by seismic-induced sidesway collapse in the P-delta mode, and in many of these cases, cyclic component material deterioration can be disregarded.

However, this consideration not only depends on the structure characteristics but also on the ground motion applied to the structure. For example, if a strong-motion earthquake causes structural collapse after a few load cycles, component degradation is of minor significance compared to a situation where a long-duration earthquake exhibits many cycles before the structure fails.

In an inelastic SDOF system, the gravity load generates a uniform shear deformation of its hysteretic force–displacement relationship, as shown exemplarily in Fig. 11, for the backbone curve of an inelastic SDOF system. Characteristic displacements (such as the yield displacement) of this relationship remain unchanged, whereas the characteristic forces (such as the strength) are reduced. As a result, the slope of the elastic and post-elastic branch rotates. The magnitude of this reduction can be expressed by means of the stability coefficient θ (MacRae 1994). The parameter θ is a function of the gravity load, geometry, and stiffness. For instance, for the bilinear SDOF system shown in Fig. 12a, the stability coefficient reads as

$$\theta = \frac{Ph}{k_r} \quad (5)$$

where P is the gravity load, h the length of the rod, and k_r the initial stiffness of the elastoplastic rotational spring at the base. In the example of Fig. 12, the post-yield stiffness is negative, because the stability coefficient θ is larger than the hardening ratio α . In a nonmaterial degrading SDOF system, a negative post-tangential stiffness ratio, i.e., $\theta - \alpha > 0$, is a necessary condition for potential structural collapse under severe earthquake excitations.

Seismic Collapse Assessment,

Fig. 11 P-delta effect on the backbone curve of an inelastic SDOF system (Modified from Ibarra and Krawinkler 2005)

Seismic Collapse Assessment, Fig. 12 (a) Model of an SDOF system vulnerable to P-delta. (b) Normalized bilinear cyclic structural behavior of an SDOF system with and without P-delta (With permission from Adam and Jäger 2012a)

Adam and Jäger (2012a) showed that the collapse capacity of a P-delta vulnerable inelastic SDOF system with non-deteriorating hysteretic behavior and bilinear backbone curve is a function of the negative slope of the post-tangential stiffness ratio $\theta - \alpha$, the elastic structural period of vibration T , the viscous damping coefficient ζ , and the shape of the hysteretic loop such as bilinear, peak oriented, or pinching. Based on this observation, Adam and Jäger (2012a) and Jäger

and Adam (2013) conducted a rigorous parametric IDA study to reveal the impact of characteristic parameters (i.e., period T , negative post-yield stiffness ratio $\theta - \alpha$, damping ζ , and hysteretic loop) on the collapse of those systems, presenting the outcomes in the form of “collapse capacity spectra.”

In a collapse capacity spectrum, the P-delta vulnerable SDOF system collapse capacity is represented as a function of the initial period of

Seismic Collapse Assessment, Fig. 13 (a) IDA curves of an SDOF system with parameters defined in the figure for all records of the FEMA P-695 far-field ground motion

set and statistically evaluated results. (b) Corresponding median “instability collapse” capacity spectrum (With permission from Adam 2014)

Seismic Collapse Assessment,

Fig. 14 Median collapse capacity spectra (blue lines) for a set of negative post-yield stiffness ratios and corresponding smooth collapse capacity spectra (With permission from Adam 2014)

vibration T for a fixed set of characteristic parameters. For example, Fig. 13a shows the individual IDA curves of an SDOF system for the 44 ground motions of FEMA P-695 far-field set (in Adam and Jäger (2012a) referred to as ATC63-FF set) up to “instability collapse,” as well as median, 16th, and 84th percentile curves. Collapse capacity spectra are obtained by repeating this procedure for different vibrational periods within a certain interval. As before, collapse capacity spectra can be computed for a specific suite of earthquake records, leading to median, 16th, and

84th percentile collapse capacity spectra (Fig. 13b). Based on a collapse capacity spectrum database, Adam and Jäger (2012a) and Jäger and Adam (2013) formulated analytical expressions of median, 16th, and 84th percentile collapse capacity spectra with a “smooth” shape via nonlinear regression analyses, as shown in Fig. 14.

In multistory frames, gravity loads may substantially impair the complete structure or only a subset of stories (Gupta and Krawinkler 2000). The local P-delta effect may induce collapse

Seismic Collapse Assessment, Fig. 15 Global pushover curves disregarding P-delta (*black graphs*) and considering P-delta (*red graphs*) (With permission from Adam 2014)

of a structural element, without necessarily affecting the stability of the complete structure. An indicator of the severity of the local P-delta effect is the story stability coefficient proposed in the Eurocode 8 (CEN 2005). However, a consistent relationship between the local P-delta effect and the global P-delta effect, which characterizes the overall impact of gravity loads on the structure, cannot be established due to dynamic interaction between adjacent stories in a multistory frame structure (Gupta and Krawinkler 2000).

Strong evidence for the vulnerability of a regular frame structure to P-delta-induced global seismic collapse is obtained from a first-mode pushover analysis (Adam and Jäger 2012b). For instance, the red curve of Fig. 15 illustrates the global pushover curve of a very flexible structure that exhibits a negative post-yield stiffness due to effect of gravity loads. When severe seismic excitation drives the structure into its inelastic branch, a state of dynamic instability may be approached, and the global collapse capacity is attained at a rapid rate. The pushover curve plotted in black

disregards gravity loads in the nonlinear static analysis.

Global pushover curves of multi-degree-of-freedom (MDOF) structures do not exhibit a uniform stability coefficient in the entire range of elastic and inelastic deformations, unlike SDOF systems. As observed in Fig. 15, two stability coefficients can be identified in a bilinear approximation of pushover curves with and without P-delta effect, that is, a stability coefficient in the elastic range of deformation (θ_e) and a stability coefficient in the post-yield range of deformation (θ_i). According to Medina and Krawinkler (2003), θ_i can be much larger than θ_e : $\theta_i > (>) \theta_e$.

Variance of Collapse

Earlier studies on quantification of epistemic uncertainties on the seismic response concluded that the contribution of epistemic uncertainties to the variance of the system's seismic performance is in general much smaller than that from aleatory uncertainties, and thus it can be omitted

Seismic Collapse Assessment,

Fig. 16 Collapse fragility curves considering the RTR uncertainties only (red line, red markers) and combined RTR and epistemic uncertainties (black lines)

(e.g., Esteva and Ruiz 1989). In contrast, recent studies indicate that the epistemic uncertainty caused by degrading nonlinear system parameters is very relevant when assessing the total variance of the collapse limit state (Ibarra and Krawinkler 2005; Zareian et al. 2010). For example, Haselton et al. (2011) evaluated the total variance of collapse capacity of a four-story reinforced concrete special moment frame, including RTR variability and modeling uncertainties. He estimated the logarithmic standard deviation associated with modeling uncertainties as 0.45, a value comparable to the standard deviation of the logarithm of RTR variability, which varies in general between 0.25 and 0.45 (Liel et al. 2009; Adam and Jäger 2012a). As an example, Fig. 16 shows the collapse fragility of a P-delta vulnerable SDOF structure as shown in Fig. 12a, considering the RTR uncertainty only, and the total variability considering RTR and epistemic uncertainties.

The effect of RTR variability on the variance of collapse is directly obtained by performing IDAs for a set of ground motions on a deterministic system. The variance of collapse capacity of nonmaterial deteriorating systems is also affected by uncertainty in parameters, such as the yield moment and post-yield hardening ratio, but their effect on the variance of collapse capacity is small compared to that originated by RTR variability.

For deteriorating models, however, epistemic uncertainty can be relevant for collapse capacity evaluation because of the large uncertainty on degrading nonlinear parameters, such as plastic rotation and post-capping stiffness (Fig. 17) (Ibarra and Krawinkler 2011; Uguirhan et al. 2014).

The first-order second-moment (FOSM) method (e.g., Melchers 1999) can be used to compute the additional variance of collapse capacity due to uncertainty in the system parameters. The total variance of the collapse capacity, $\sigma_{\ln CC(TOT)}^2$, based on FOSM is (Ibarra and Krawinkler 2011):

$$\sigma_{\ln CC(TOT)}^2 \cong \sum_{i=1}^n \sum_{j=1}^n \left(\frac{\partial g(\bar{X})}{\partial x_i} \frac{\partial g(\bar{X})}{\partial x_j} \right)_{\bar{X}=\bar{\mu}_x} \rho_{x_i, x_j} \sigma_{x_i} \sigma_{x_j} + \sigma_{\ln CC(RTR)}^2 \quad (6)$$

The first term on the right hand side of Eq. 6 represents the contribution to the variance of collapse capacity due to uncertainty of the system parameters, whereas $\sigma_{\ln CC(RTR)}^2$ is the contribution to the variance of collapse capacity due to RTR variability, and $\bar{X}$ represents the set of system random parameters. The function $g(\bar{X})$ is the collapse capacity as a function of the variation on system parameters, and the variance is computed from the gradient of $g(\bar{X})$, which is

Seismic Collapse Assessment,

Fig. 17 Uncertain parameters of the backbone curve (Modified from Ibarra and Krawinkler 2005)

linearized using a Taylor series expansion about the mean $\bar{X}$. The derivative $\partial g(\bar{X})/\partial x_i$ can be approximated by evaluating the performance function at two system parameter values. The derivative is estimated as the slope of the straight line that connects the pairs $[x_i, g(x_i)]$. The standard deviation of the system parameters, σ_{x_i} , and the correlation coefficients, ρ_{x_i, x_j} , need to be estimated in advance.

Ibarra and Krawinkler (2005, 2011) used the FOSM method to evaluate the effect of uncertainty in system parameters on the collapse capacity of SDOF systems. They found that uncertainty in the displacement at the peak (cap) strength and the post-capping stiffness contributes significantly to the variance of collapse capacity. The uncertainty in deterioration parameters on the variance of collapse capacity may be comparable to that caused by RTR variability.

Although the FOSM method is relatively simple to implement, it cannot predict the shift in the median caused by system uncertainties. Vamvatsikos and Fragiadakis (2010) concluded that this shortcoming should not be considered important for practical applications because for more cases the shift in the median is less than 10 %. Liel et al. (2009) found shifts in the median closer to 20 % and proposed a simplified method, termed ASOSM (approximate second order second moment), that uses FOSM to predict the increase in fragility's logarithmic standard deviation and the shift in the median of the limit state fragility. The total variance can also be approximated using the point estimate method, in which

the first moments of a function are calculated in terms of the first moments of the random variables (Rosenblueth 1981). The total variance in collapse capacity can be more accurately predicted using Monte Carlo simulation, but this method is computationally expensive. An alternative is to use the Latin hypercube sampling (LHS) method to reduce Monte Carlo realizations. LHS is a stratified sampling that allows efficient estimation of the quantity of interest by reducing the variance of Monte Carlo simulations (Vamvatsikos and Fragiadakis 2010). In the example of Fig. 16, the FOSM method and the LHS method deliver almost the same prediction of the collapse fragility function.

Simplified Methods

IDA and MSA procedures require the numerical solution of the governing equations of motions of the structural model together with constitutive equations in each time step for each response history analysis. As a consequence, it is time-consuming and computationally expensive. Thus, there is a need for simple to apply, but yet sufficient accurate methods to predict the global collapse of MDOF structures under seismic excitations (Lignos and Krawinkler 2012).

Methods Based on Nonlinear Static Analysis

One of the simplest approaches is to conduct a nonlinear static analysis to estimate the seismic collapse capacity. During this so-called pushover

Seismic Collapse Assessment, Fig. 18 Global pushover curve up to global collapse (With permission from Adam 2014)

analysis, gravity loads are applied to the structural model that considers explicitly the inelastic constitutive behavior of its elements. Subsequently the model is subjected to lateral forces with a predefined invariant load pattern that is amplified incrementally in a displacement-controlled procedure. A first-mode load pattern may be used. Alternatively, the load pattern recommended in ASCE 7-10 (2010) can be utilized. As a result the global pushover curve of the structure is obtained, at which the base shear is plotted against the displacement of the control node (usually the roof displacement). The global pushover curve represents the global capacity of the building against horizontal loads, and it is assumed that it reflects the global or the local mechanism involved when the structure approaches dynamic instability. In the perspective of a “near-collapse” limit state, collapse is assumed if one of the selected EDPs, such as story drifts, plastic hinge rotations, etc., exceeds a certain threshold. When the base shear drops to zero (Fig. 18), global “instability collapse” is assumed to be attained.

Pushover analysis was originally developed for first-mode dominated structures and later refined to account also for higher mode effects (e.g., Chopra and Goel 2002). The basic assumption of these procedures is that the nonlinear static response can be related to the nonlinear dynamic response. This is, however, not the case for many structures because the dynamic response is strongly path dependent, and effects, such as cyclic deterioration, damping, and duration of an earthquake, among others, cannot be captured. Nonetheless, nonlinear static analysis

may be reasonable applied as an ingredient for the collapse assessment of regularly shaped low-rise buildings whose seismic response is dominated by the first mode. Even if the pushover procedure is not appropriate for a full collapse assessment, it can be used to identify weaknesses in the structural design, to debug a structural model used for collapse assessment, and to obtain a better understanding of the strength and deformation demands of the structure (Deierlein et al. 2010). In contrast, Villaverde (2007) states that it is doubtful that nonlinear static methods can be used reliably to predict the seismic collapse capacity of structures and to estimate their margin of safety against a global collapse. These methods, however, are commonly utilized in practical procedures. For example, Shafei et al. (2011) proposed a simplified methodology for collapse assessment of degrading moment-resisting frames and shear walls utilizing closed-form equations, given that the global pushover curve is provided. These equations correlate median and dispersion of collapse fragility curves and were generated through multivariate regression analysis from a comprehensive database of collapse fragilities and pushover curves.

Methods Based on Equivalent Single-Degree-of-Freedom Systems

Several studies use equivalent single-degree-of-freedom (ESDOF) systems to predict the global seismic collapse capacity (e.g., Bernal 1998; Fajfar 1999; Adam et al. 2004). Application of ESDOF systems implies that the first mode dominates the dynamic response and the collapse mode. A global collapse capacity assessment of low- to medium-rise buildings by means of an ESDOF system is straightforward when the story drifts remain rather uniformly distributed over the height, regardless of the extent of inelastic deformation. Adam and Jäger (2012b) showed that the application of these simplified systems yields reasonable collapse capacity predictions for P-delta-sensitive regular high-rise buildings, because P-delta-induced collapse is primarily controlled by the first mode. However, if a partial mechanism develops, the global collapse capacity is greatly affected by the change of the

deflected shape, and it will be amplified in those stories in which the drift becomes large (Bernal 1998).

Capacity Spectrum Method (N2 Method)

In the last decade, the capacity spectrum methodology became a popular tool for assessing the seismic performance of regular first-mode dominated structures. It represents a compromise between nonlinear dynamic analyses with complex modeling strategies and simplified linear static analysis methods. In Eurocode 8 (CEN 2005), a version of this method, i.e., the N2 method (Fajfar 1999), is implemented.

In this approach a global lateral load–displacement relation, which is the outcome of a pushover analysis, represents the seismic capacity of the structure and is referred to as capacity curve. The base shear V and the roof displacement x_N of a bilinear idealization of this curve are transformed into the domain of the corresponding ESDOF system according to the following Eurocode 8 equations (CEN 2005) (see Fig. 19):

$$\begin{aligned} f^* &= V/\Gamma, & D &= x_N/\Gamma, \\ \Gamma &= L^*/m^*, & L^* &= \sum_{i=1}^N m_i \phi_i, & m^* &= \sum_{i=1}^N m_i \phi_i^2 \end{aligned} \quad (7)$$

Here, f^* is the equivalent spring force, and D the displacement of the ESDOF system. The equation includes the story masses m_i , $i = 1, \dots, N$, of the ductile N -story structure, and the N components ϕ_i of the shape vector ϕ (with $\phi_N = 1$), which prescribes the vertical distribution

of the displacements of the structure in its ESDOF approximation (Fajfar 2002). Note that ϕ should be affine to the horizontal load pattern of the pushover analysis.

Dividing f^* by the equivalent mass L^* renders its ordinate in the “acceleration” dimension; see Fig. 19. This transformation permits the comparison of the capacity curve with the seismic demand represented by the response spectrum in the ADSR format of the actual site. In this format for an inelastic SDOF system with a target ductility μ , the spectral acceleration S_{av} at yield is plotted against the corresponding peak spectral displacement S_d (Fajfar 1999), as shown in Fig. 20a. Note that the ductility defines the ratio of the maximum imposed (inelastic) deformation to the deformation at onset of yield.

In the subsequent step, the intersection point between a bilinear approximation of the capacity curve and the response spectrum is obtained. If this point is in the inelastic branch of deformation, the elastic spectrum must be reduced such that the ductility of the capacity curve at this point and of the corresponding inelastic spectrum coincide, Fig. 20b. For periods larger than the corner period T_c , this intersection point, which is referred to as performance point, is found by application of the equal displacement rule.

According to Eurocode 8 (CEN 2005), structural stability under seismic excitation cannot be verified if the displacement demand at the performance point is larger than two-thirds of the ultimate deformation capacity of the structure or if no performance point can be found. Consequently, collapse is indicated, as presented in Fig. 20b.

Collapse Capacity Spectrum Method

The collapse capacity spectrum method is another example of a simplified ESDOF system-based method. This method predicts the global collapse capacity of regular P-delta-sensitive moment-resisting frame structures, where cyclic component deterioration can be omitted (Adam and Jäger 2012b). In a first step, the vulnerability of the structure to P-delta-induced collapse is evaluated based on global first-mode pushover curve of the structure with applied gravity loads. When this curve exhibits a negative post-yield stiffness, as shown in Fig. 15, the building may collapse under severe earthquake excitation in the P-delta mode. In this situation the structure is transformed into an ESDOF system.

Collapse capacity spectra (Adam and Jäger 2012a) are the further ingredient of this method. However, application of collapse capacity spectra is not straightforward for an MDOF structure, because the backbone curve of the ESDOF system is derived from the global first-mode pushover curves with and without considering P-delta. As discussed before, bilinear idealization of these curves does not exhibit a uniform stability coefficient as in a real SDOF system, but an elastic θ_e and an inelastic stability coefficient θ_i that is always larger, in some cases even much larger than θ_e : $\theta_i > (>) \theta_e$. Assigning a specific auxiliary backbone curve (Ibarra and Krawinkler 2005) to the ESDOF system solves this problem because its rotation by the uniform auxiliary stability coefficient θ_a ,

$$\theta_a = \frac{\theta_i - \theta_e \alpha_s}{1 - \theta_e + \theta_i - \alpha_s} \quad (8)$$

yields the backbone curve considering P-delta in analogy to a real SDOF system; see Fig. 21. The parameter α_s is the strain-hardening coefficient of the global pushover curve without P-delta. The discussed backbone curves of the ESDOF system are depicted in Fig. 21: The bilinear curve with the largest strength represents the auxiliary backbone curve, and the graph with the smallest strength is the backbone curve with P-delta. Subsequently the negative post-yield stiffness ratio $\theta_a - \alpha_s$ of the auxiliary ESDOF system is evaluated. Since the initial stiffness of the auxiliary backbone curve is larger than the original one, the period of the ESDOF system with assigned auxiliary backbone curve is (Adam et al. 2004)

$$T_a = 2\pi \sqrt{\frac{1 - \alpha_s}{1 - \theta_e + \theta_i - \alpha_s}} \sqrt{\frac{x_{Ny}}{V_y}} \sqrt{\sum_{i=1}^N \phi_i m_i} \quad (9)$$

In Eq. 9 x_{Ny} and V_y denote the roof displacement and the base shear, respectively, at the onset of yield of the global pushover curve without P-delta; see Fig. 15.

Now the appropriate collapse capacity spectrum with respect to the underlying ground motion set, viscous damping ζ , the hysteretic loop, and the negative post-yield stiffness $\theta_a - \alpha_s$ is consulted to obtain the median (CC_d), 16th

Seismic Collapse Assessment,

Fig. 21 Backbone curves with and without P-delta and auxiliary backbone curve (Modified from Adam and Jäger 2012b)

(CC_d^{p16}), and 84th percentile (CC_d^{p84}) collapse capacities of a SDOF system at the period T_a of the auxiliary ESDOF system. For instance, in Fig. 14 CC_d is read at a period $T_a = 3.2$ s for $\theta_a - \alpha_S = 0.20$. These collapse capacity quantities are transformed into the domain of the ESDOF system:

$$CC_{\text{ESDOF}} = \frac{CC_d}{\lambda_{\text{MDOF}}},$$

$$\lambda_{\text{MDOF}} = \left(\sum_{i=1}^N \phi_i m_i \right)^2 / \left(\sum_{i=1}^N m_i \sum_{i=1}^N \phi_i^2 m_i \right) \quad (10)$$

λ_{MDOF} is the transformation coefficient that relates the actual structure with the corresponding SDOF system. For details it is referred to Fajfar (2002). CC_{ESDOF} is an estimate of the median collapse capacity of the MDOF system, $CC_{\text{MDOF}} \approx CC_{\text{ESDOF}}$. The same applies to the percentiles: $CC_{\text{MDOF}}^{p16} \approx CC_{\text{ESDOF}}^{p16}$ and $CC_{\text{MDOF}}^{p84} \approx CC_{\text{ESDOF}}^{p84}$. Since the collapse capacities follow generally a log-normal distribution, an approximation of the collapse fragility function is derived from

$$\ln N(m, \sigma^2), \quad m = \ln(CC_{\text{ESDOF}}),$$

$$\sigma = \ln \sqrt{CC_{\text{ESDOF}}^{p16} CC_{\text{ESDOF}}^{p84}} \quad (11)$$

Application of this method for assessing the seismic collapse fragility of a series of generic

and real moment-resisting frame structures showed that the collapse capacity can be estimated quick, but yet accurate, without conducting time-consuming dynamic analyses (Adam and Jäger 2012b). The collapse capacity spectrum method is particularly useful in engineering practice because the structure can be evaluated with respect to its seismic collapse capacity in the initial design process without a detailed dynamic analysis.

Summary

This article summarizes procedures currently used for assessing global collapse of structures induced by strong-motion earthquakes. Through intensive research in the last two decades, substantial progress was achieved in this field, and the outcomes of these studies are compiled in numerous publications. Thus, in the present contribution, only some of the issues involved in seismic collapse assessment are elaborated in detail. The selection of the presented material is naturally biased by research and experience of the authors.

Seismic collapse assessment is a branch of earthquake engineering that combines multidisciplinary fields of research such as seismology, structural dynamics, materials science, applied mathematics, and computational mechanics. It includes adequate prediction of the seismic hazard, ground motion selection, identification of

possible modes of collapse, modeling of cyclic component deterioration, appropriate consideration of hysteretic and viscous damping, quantification of modeling and parameter uncertainties, and nonlinear dynamic analyses based on stable numerical algorithms.

For accurate assessment of seismic structural collapse, however, there are still challenges that need to be addressed. For example, understanding of nonlinear cyclic component behavior in a condition of oblique bending requires experimental tests and advances in constitutive modeling. Another issue is the quantification of the contribution of nonstructural elements on the seismic collapse capacity. On the other hand, from engineering practice, there is a strong demand on simplified assessment strategies that are simple to apply and at the same time reasonably accurate.

Introduction

Design of new dams or safety evaluation of existing dams for seismic loads is standard practice and routinely required. In a broad term, dams can be classified into three types – concrete dam, rock-fill dam, and earthfill dam – and seismic design can be at a dam safety level and/or at a serviceability level.

This entry provides contents and discusses methods for design and analysis of earthfill dams at a dam safety level where the ultimate limit state is applied for the highest level of design earthquake loads. For dam safety, dam failure is the primary concern; for serviceability consideration, the dam should remain functional and any damages should be easily repairable under this level of earthquake loads.

Dam Performance in Past Earthquakes

Damages to dams under earthquakes can result from ground shaking, soil liquefaction, ground cracking, ground displacements (lateral spreading and settlement), and in extreme cases surface rupture along an earthquake-active fault. Examples of recent big and devastating earthquakes include the 2008 Sichuan earthquake (a crustal

earthquake with a magnitude of M8.0 occurred in China) and the 2010 Chile earthquake (a subduction earthquake with M8.8 occurred off the coast of central Chile).

Historical data show that dams around the world have performed well and satisfactory and that the probability of a dam failure under strong ground motion shaking is low. Nearly all well-built and well-compacted embankment dams can withstand moderate earthquake shaking with peak ground accelerations (PGA) greater than 0.2 g. Dams constructed of clay soils on clay, or on rock, or on overburden foundations resistant to liquefaction have withstood (with no apparent damages) extremely strong shaking with PGAs from 0.35 to 0.8 g.

Soil liquefaction, either in the dam fills or in the foundation, is the most damaging factor that affects the performance of dams under earthquakes. Dams built of sandy soils, especially hydraulic or semi-hydraulic fills, or built on foundations of loose (low density) sandy soils are highly susceptible to earthquake damage or vulnerable to failures due to the potential for soil liquefaction. A famous case history of such is the near failure of the Lower San Fernando Dam in California, USA, in a 1971 earthquake (Seed 1979).

Design Seismic Loads Based on a Risk Analysis

Public tolerance to seismic risk for the consequence of dam failure ultimately determines the adequacy of an existing dam or the criteria for the design of a new dam. For instance, at a specific location with the same tectonic setting or geological condition and thus the same earthquake hazard condition, a nuclear reactor facility may be designed using a PGA of 1.0 g for a very low probability earthquake event, a hydroelectric dam using a PGA of 0.7 g for a low probability earthquake event, a residential building using a PGA of 0.5 g for a median probability of happening, and a temporary bridge for construction traffic using a PGA of 0.3 g for a relatively high probability of

occurring. This is mainly because the societal risk tolerance on a relative scale increases in order from nuclear radiation leak to flood from a dam breach, to collapse of a residential building, and to loss of a temporary structure.

The first factor contributing to seismic risk, such as from an earthquake event with a PGA of 0.7 g, is the occurrence rate of such earthquake which is often measured by annual exceedance probability (AEP). The other factor is the consequence as a result of an earthquake, which is ultimately measured in terms of loss of life and sometimes economic loss. At a conceptual level, seismic risk can be expressed as the product of seismic hazard probability and consequence, and it represents the probabilistic expectation of the consequence.

Ideally, seismic design of a dam should be based on a risk analysis, including calculation of the actual probability of a dam failure and its consequence. The adequacy of the dam would then be judged from the seismic risk (such as annual probability of single or multiple fatalities) that is acceptable to the society for the loss of life involved in a dam failure.

The risk-based approach to dam safety evaluation should balance the public risk and the limited societal resources available to manage the particular risk. As shown in Fig. 1, it is considered generally acceptable that the maximum level of societal risk to fatality is less than 10^{-3} per annum for loss of one life and the risk is less than 10^{-5} per annum when more than 100 lives would be lost in the event of a dam failure. The principle that the risks should be as low as reasonably practicable (ALARP) is generally followed in practice, and it is thus reasonable to use an annual probability of 10^{-5} and 10^{-6} for 100 and more fatalities.

In mathematical terms, seismic risk to loss of life (fatality) is calculated using the following two equations:

$$P_{\text{Fatality}} = P_{\text{Failure}} \times P_{\text{Fatality/Failure}}$$

and

$$P_{\text{Failure}} = P_{\text{Earthquake}} \times P_{\text{Failure/Earthquake}}$$

Seismic Design of Dams,
Fig. 1 An example
 relationship to manage
 societal risk for dam safety

where:

P_{Fatality} = unconditional probability of fatality from earthquake, i.e., seismic risk.

$P_{\text{Earthquake}}$ = unconditional probability for an earthquake to occur, such as the one with a PGA of 0.7 g.

$P_{\text{Failure/Earthquake}}$ = conditional probability of a dam failure in event of the earthquake.

$P_{\text{Fatality/Failure}}$ = conditional probability of loss of life in the event of a dam failure.

The probabilities caused by all dam failure initiating events (failure modes) need to be aggregated or compounded in order to obtain the total probability to a dam failure. Failure modes (such as soil liquefaction) for earthquake loading should be identified in advance in order to perform a risk calculation. The risk calculation for a particular failure mode (P_{Failure}) is carried out using an event tree approach where significant events are sequenced in levels. Construction of an event tree for a dam requires special knowledge in geotechnical earthquake engineering and a comprehensive understanding of the dam.

Using “soil liquefaction” as an example failure mode, an event tree for dam failure could consist of earthquake acceleration (Level 1), contributing earthquake magnitude (Level 2), liquefaction analysis method (Level 3), soil

liquefaction capacity (Level 4), dam crest settlement magnitude (Level 5), reservoir water level (Level 6), and dam damage level (Level 7). For illustration purpose, at Level 1 for earthquake acceleration, it may have four scenarios with a PGA of 1.0, 0.7, 0.5, and 0.3 g, respectively, and each PGA scenario has its probability of occurrence (AEP). At Level 3 assuming two models for liquefaction analysis, the weighting factors (e.g., 0.55 and 0.45) would be assigned to each model to make a total weighting of 1.

In many cases where a dam consequence class is available after completion of a life safety model and analysis, it can be conservatively assumed that the conditional probability ($P_{\text{Fatality/Failure}}$) equals to 1.

Although in recent years the risk-based seismic dam safety evaluation is increasingly used in dam safety management, it is not widely used in engineering design or seismic safety evaluation due to the limited ability to perform such a complex risk-based analysis. As described below, the standard-based or traditional approach is more commonly used in seismic design.

Standard-Based Method and Design Earthquake AEP

The standard-based method is a semi-probabilistic method that defines the seismic

hazard using the probabilistic approach, but does not explicitly calculate the probability of a dam failure and its consequence. Without any quantifiable risk calculation, this is an empirical or experience-based approach to risk evaluation and management. The consequence, i.e., conditional fatalities in the event of a dam failure, is indirectly evaluated by using a dam consequence class scheme (FEMA 1998; CDA 2007). In some countries the highest consequence class is “Extreme” when potential (expected) fatalities are 100 and more.

With this approach, a seismic hazard level (AEP) is selected according to the consequence class of a dam so that the selected AEP conforms to the societal acceptable risk level. For a dam under an “Extreme” class, it would be reasonable to target a dam failure probability of 10^{-5} to 10^{-6} per annum, and an earthquake with an AEP of 10^{-5} or higher could be adequate, taking into account the satisfactory post-earthquake performance of dams around the world, i.e., the low conditional probability of a dam failure under strong shaking. For background information, the nuclear industry uses the 84th percentile spectra at AEP of 10^{-4} or approximately median-mean spectra at a probability of 10^{-5} per annum. With less stringent safety criteria than the nuclear industry, dam safety design can adopt a design earthquake with an AEP of 1/10,000 (i.e., 10^{-4}) based on the mean spectra. The mean is the expected value given the epistemic uncertainties, and the mean hazard value typically such as in Canada varies from 65th to 75th percentiles in the hazard distribution.

The design earthquake AEP for an “Extreme” class dam can vary from one region to another or from one country to another depending on the risk tolerance ability, and it is normally jointly selected by the dam owner and the government regulatory agency. In some developing countries with lower societal reliability than the developed countries, an earthquake AEP of 1/1,000 is used for dam safety design. On the other hand, even in developed countries such as Canada, an earthquake AEP of 1/2,475 is used for building safety design as a result to balance public risk and economic cost.

Once a seismic hazard level is selected, conventional analyses such as limit equilibrium or finite element analyses are conducted using seismic loads corresponding to the selected AEP. The results (such as stresses, ground displacements, or stability in a dam or its foundation) and consequences are evaluated deterministically using standards, specifications, and design codes. The potential for a dam failure is evaluated by comparing deterministically the resulting stresses and displacements with ultimate stability and established failure criteria. The evaluations of results are primarily done by empirical evidence, past experience, and engineering judgment.

Seismic Hazard Evaluations

A deterministic seismic hazard analysis (DSHA) is normally conducted for each known earthquake source to determine site ground motion parameters such as PGA, response spectra at 50th and 84th percentile, magnitude of earthquake, and duration of strong shaking. This would include assessment of potential seismic hazards from earthquake activities along local or regional known faults for the life of a dam.

A probabilistic seismic hazard analysis (PSHA) is usually conducted to determine design seismic parameters at various AEP levels, in addition to DSHA where known active faults or subduction zones are identified. A PSHA normally consists of **identification** of earthquake sources by developing a source model and the earthquake occurrence rate for each source zone with the understanding of local geology and regional past earthquake history, **application** of ground motion prediction equations (Earthquake Spectra 2008) that are appropriate to the region (e.g., hardness and shear wave velocity of the bedrock) and the types of seismic sources, and **determination** of earthquake response spectra at various levels of probability by the integration of hazard contributions over all earthquake magnitudes and distances for all seismic source zones.

The response spectra, either from DSHA or from PSHA, are normally defined for a series of discrete natural periods or frequencies (such as

Seismic Design of Dams,
Fig. 2 Example results of
seismic hazard analyses (a)
probabilistic method and
(b) deterministic approach

0.1, 0.2, 0.5, 1, 2, 5, 10, and 33 Hz; the frequency for PGAs can range from 33 to 100 Hz) that are used in the hazard calculation, and they are always associated with an uncertainty level (e.g., median, mean, or 84th percentile).

A seismic hazard analysis determines the potential intensity of seismic loads that could hit a damsite; and it always proceeds to, but does not always relate to, the design of a new dam or performance evaluation of an old dam for earthquake loading. However, seismic design of dams uses results of a seismic hazard analysis. Figure 2 shows

typical response spectra from DSHA and PSHA at the most commonly used damping ratio of 5 %.

Design Seismic Parameters

Seismic parameters for design of dams consist mainly of peak ground accelerations (PGAs), site-specific response spectra for horizontal and vertical accelerations, magnitude and site-source distance for the design earthquake, duration of strong shaking, ground motion time histories as

required for dynamic analyses, and fault displacements in rare situations when a dam is (or to be) on an active fault.

Design Response Spectra and PGAs

Response spectra and PGAs from DSHA can be used directly in seismic design, and they are conventionally computed at an 84th percentile value in the hazard distribution, i.e., one standard deviation (using $\varepsilon = 1$ in ground motion prediction equations) above the predicted median value. In some cases for seismic faults with low rate of activities, the 50th percentile values (the median) are used in design.

When seismic hazard is evaluated using a probabilistic approach, response spectra and PGAs from PSHA are used for seismic safety design of dams, using the results for the selected AEP (e.g., mean spectra with AEP of 1/10,000).

In current practice, the vertical ground motions do not seem to have much effect on the performance of earthfill dams and thus are not normally included in design analysis.

Design Earthquake Magnitude and Site-Source Distance

The PSHA results represent at a specific AEP level a composite of hazard contributions from earthquakes of all magnitudes and distances. The response spectra from a PSHA are also called the uniform (or equal) hazard response spectra (UHRS).

Deaggregation of the composite seismic hazard is performed to identify relative contributions of individual earthquakes or scenario earthquakes with various magnitudes and distances. For seismic design of a dam, representative earthquake magnitudes (M) and site-source distances (D) are obtained by deaggregation of the uniform hazard at natural periods that are significant and critical to the dam seismic response.

The representative M and D for the design earthquake are then used in seismic analysis where magnitude and duration of the earthquake are needed such as in the soil liquefaction analysis, or for selection of ground motion records needed in a time-history analysis.

Input Ground Motion Time Histories

The current trend in seismic design of dams is to conduct linear or nonlinear time-history analysis to obtain dynamic response of dam to earthquake loads. Time-history analysis of dam requires input ground motion time histories (acceleration, velocity, and displacement).

For dynamic analysis of earthfill dams, multiple ground motion records (five to eight commonly adopted) from past earthquake are selected, and each record is then linearly scaled to fit the design response spectra (such as a UHRS) over the range of natural periods that are appropriate for the dam. Using this method, an individual ground motion record is multiplied by a single scale factor to increase or decrease the magnitude of the motion and its spectrum, without modifying the shape of its spectrum or its frequency contents.

The selected ground motion records should be consistent with the seismic parameters and representative to the design earthquake in terms of magnitude, site-source distance, duration of strong shaking, tectonic setting and source mechanism, and consistency of site conditions between the recording station and the dam.

In some cases when uniform scaling of recorded ground motions is unable to meet the requirements, the design earthquake ground motions would be obtained by modifying a recorded ground motion in the time or frequency domain.

General Approach to Seismic Design and Analysis

For dams under static conditions, limit equilibrium analyses for slope stability are normally conducted for long-term operating reservoir conditions (steady-state seepage) and for short-term reservoir drawdown conditions. In general, for satisfactory stability factor of safety (FS) would be minimum 1.5 for long-term conditions ($FS > 1.5$) and 1.3 for short-term conditions ($FS > 1.3$).

Seismic Design of Dams, Fig. 3 Types of seismic analyses based on liquefaction susceptibility (PWP = excess pore water pressures from earthquake loads)

For dams under seismic loading, two primary modes of dam failure must be addressed, the overtopping failure caused by excessive settlement of dam crest and the internal erosion and piping failure caused by cracks in dams, damage of filter layer upstream, or drains downstream of the core zones.

Some of the common design measures to mitigate these failures include the following: remove or improve problematic foundation soils by ground treatment and adequately compact the dam fills, use wide core zones of plastic soils that are resistant to erosion, use well-graded wide filter zones upstream of the core, construct chimney drains downstream of the core to lessen soil saturation and reduce downstream seepage, and use dam crest and downstream slope details to provide protection of the dam in the event of an overtopping.

Seismic analyses appropriate to a dam and its foundation are conducted using design seismic parameters to provide adequate information on expected stresses and ground displacements for evaluation of expected performance of the dam. Seismic analyses (see Fig. 3) can include a soil liquefaction evaluation, a pseudo-static stability analysis, a Newmark sliding block deformation

analysis, a post-earthquake static stability analysis, and a finite element dynamic analysis for computing permanent ground deformations.

Evaluation of Soil Liquefaction

Liquefaction of Sands Under Cyclic Loads

Sand liquefaction is a fluidization process of saturated sand mass subject to cycles of shear stress. Under shaking, it can be easily observed that loose sands in a dry container will experience volume contraction and settle to a more compact state. In a saturated condition, immediate volume change of the sand would not occur because water in the pore does not drain quickly enough under the rapid earthquake loading. Instead, the potential for volume change translates into a quick increase in excess pore water pressure (PWP) in the sand mass. Liquefaction occurs when the PWP exceeds a threshold value that the pore water effectively suspends sand particles. Sand boiling to ground surface is a surficial expression of liquefaction of sands in the ground.

Liquefaction strength, or capacity, or resistance (more commonly used) of sands can be measured by laboratory testing using

Seismic Design of Dams,
Fig. 4 Liquefaction
resistance trend curves for
clean sands (<5 % fines)

reconstituted samples prepared to a target relative density. It is found (see Fig. 4) that liquefaction resistance generally increases with relative density as expected, and under the same relative density, it decreases with more cycles of shear stress used in the testing.

Because liquefaction is triggered by multiple cycles of shear stresses, liquefaction resistance of soils is represented using both the cyclic shear stress level (τ_{cyc}) and the number of cycles for such uniform (constant amplitude) stresses to trigger a liquefaction failure. Cyclic stress ratio (CSR) refers to the ratio of the cyclic shear stress to the initial vertical normal stress (σ'_{v0}) at which the sample is under cyclic shearing, i.e., $CSR = \tau_{cyc}/\sigma'_{v0}$. For earthquake loading, the number of cycles is related to earthquake magnitude and duration. In engineering analysis, nonuniform cycles of shear stress from a M7.5 earthquake are artificially set equal to, in terms of net effect on soil, a shear stress level with 15 uniform cycles. Thus, liquefaction resistance of soil is typically characterized by CSR at 15 cycles or CSR_{15} as shown in Fig. 5.

Liquefaction Resistance of Sandy Soils

Except with ground-frozen sampling technique that is practically not applicable, liquefaction resistance of in situ sands is considered not measurable from laboratory testing.

The most widely adopted test for field evaluation of relative density for sands is the standard penetration test (SPT) with split-barrel soil

sampling. A key result of SPT is SPT N value that is the number of blow counts for a penetration depth of 305 mm (1 ft.), and $(N_1)_{60}$ is defined as the N value corrected for the soil under an in situ effective vertical normal stress of about 100 kPa (1 atmospheric pressure) and to the standard SPT hammer energy level (i.e., at 60 % of the theoretic maximum hammer energy). The general understanding is that the measured SPT N value is corrected downward (i.e., reduced) when the test is performed for soil at a depth with a confining stress higher than 100 kPa (e.g., at 300 kPa).

Current technology or methodology for evaluating liquefaction resistance of sandy soils was developed empirically by indirect studies of performance case histories of dams in historical earthquakes, where in some cases soil liquefaction was assessed to have occurred and in other cases liquefaction was believed not triggered.

Field soil liquefaction resistance of sands (particle size from 0.075 to 4.75 mm) has been derived from field performance of soils under various levels of historical earthquakes, and CSR_{15} from case history studies is plotted with in situ measured $(N_1)_{60}$ (Seed and Harder 1990) as an equivalence to the relative density of sand. Similar to the curve shown in Fig. 5, sands with $(N_1)_{60} > 30$ are considered to be dense and generally not liquefiable; sands with $(N_1)_{60} < 10$ are generally loose and highly susceptible to liquefaction.

Seismic Design of Dams,

Fig. 5 An example liquefaction resistance curve for clean sands

Unless completely confined with no drainage path, gravels (particle size from 4.75 to 75 mm) are not so much vulnerable to soil liquefaction due to its high permeability that allows fast dissipation of excess pore water pressures. However, sandy soils containing some amount of gravels are liquefiable, and their liquefaction resistance can be tested in the field using a large penetration hammer such as the Becker Hammer Penetration Test (Youd et al. 2001).

At a given relative density or $(N_1)_{60}$, sandy soils containing significant amount of fines (particle size < 0.075 mm) are known to have higher liquefaction resistance than clean sands with no fines (Youd et al. 2001). Nonplastic silts, containing 100 % fines but with very low plasticity (such as plasticity index $PI < 5$ %), are considered to behave under cyclic loading in a similar manner as sands. The liquefaction resistance of nonplastic silts is evaluated as sands with upward correction on fines content.

Liquefaction Resistance of Plastic Soils

A more descriptive terminology for liquefaction failure of plastic soils (silts or clayey silts), containing 100 % fines and with relatively high PI (such as $PI > 10$ %), is “cyclic strain softening” which emphasizes more on the structural breakdown of the material under cyclic loading than on the buildup of excess pore water pressure. Evaluation of liquefaction resistance for plastic soils is an area that requires more research. In the

1980s and 1990s of the last century, soil index parameters (water content, liquid limit, PI , and fines content) were used as basis for liquefaction assessment, but the current trend method is to use results of laboratory cyclic tests (Finn and Wu 2013), especially for evaluation of more critical structures such as for dam safety.

Liquefaction resistance of in situ plastic soils can be measured directly by laboratory testing on in situ Shelby samples. Soil samples in a cyclic direct simple shear test are normally first consolidated to its pre-consolidation pressure (the highest historic pressure experienced by the soil or σ'_p) and then sheared by cycles of τ_{cyc} under σ'_{v0} and initial shear stress (τ_{st}) similar to the in situ stresses of the sample.

As compared to sands where the relative density or $(N_1)_{60}$ is the single parameter, there are more parameters and factors affecting and contributing to the liquefaction resistance for plastic soils (see Fig. 6). The curves for plastic soils are generally flatter than curves for sands; that is, the resistance decreases less with increasing number of cycles. The two key factors are the over-consolidation ratio ($OCR = \sigma'_{v0}/\sigma'_p$) and PI . Liquefaction resistance of plastic soils generally increases with increasing OCR and PI but decreases with increasing τ_{st} .

As a general observation, plastic soils having $CSR_{15} > 0.4$ (for 15 cycles) are considered to be hard, insensitive to earthquake loading, and unlikely to experience much strength loss. Plastic

Seismic Design of Dams,

Fig. 6 Liquefaction resistance trend curves for plastic soils, generally flatter than sands

soils having CSR_{15} near or less than 0.15 may be sensitive to shaking and can experience significant loss of strengths in a strong earthquake.

Earthquake-Induced CSR

For liquefaction analysis, seismic load in a soil element is represented by time history of shear stresses (τ_{dyn}) imposed by earthquake shaking, and they can be calculated from a site response analysis using the input ground motions at the damsite and dynamic properties of dam fills and foundation soils.

Soil dynamic properties for each of the soil zones in the dam and its foundation primarily consist of low-strain shear modulus (G_{max}) and the damping characteristics (Seed et al. 1986). The low-strain shear modulus (G_{max}) is commonly computed from shear wave velocity (V_s) that can be measured by seismic downhole or crosshole surveys. Shear modulus would reduce from G_{max} as shear strain increases; reduction of soil shear modulus (stiffness) with increasing strains is more significant for gravels than for sands and more for sands than for clays. Soil damping ratio would be less than 5 % at low strain, but it increases with increasing strain. The maximum damping ratio is about 25 % for gravels and sands and in the order of 20 % for clays and silts.

A seismic site response analysis (► [Site Response: 1-D Time Domain Analyses](#)) is commonly performed in a total stress analysis, without including PWP effect, using a 1D soil column

analysis for a low dam or using a 2D finite element dynamic analysis to model the geometric effect for a high dam. A site response analysis, either 1D or 2D model, can be conducted using the equivalent linear method (Idriss et al. 1974) or a true nonlinear method (Finn et al. 1986) for the simulation of shear modulus degradation (decrease) and damping ratio increase with the increase of shear strain. A true nonlinear approach is considered more appropriate when the ground shaking level is high, such as with a PGA of 0.4 g or higher.

Factor of Safety Against Liquefaction

Upon completion of a site response analysis, cyclic stress ratio ($CSR = \tau_{dyn}/\sigma'_{v0}$) in each soil zone is calculated by converting the nonuniform cycles of shear stresses from the earthquake to equivalent cycles of uniform shear stresses (Wu 2001) and then normalized to the in situ vertical normal stress (σ'_{v0}).

The liquefaction resistance (CSR_{15}) of soils is determined, for sands using $(N_1)_{60}$ from SPT and for plastic soils using liquefaction resistance curves from laboratory cyclic shear tests.

A factor of safety against soil liquefaction for each soil zone is calculated to be the ratio of liquefaction resistance of soil and seismic shear stress from earthquake, i.e., $FS_{LIQUEFACTION} = CSR_{15}/CSR$. A computed $FS_{LIQUEFACTION}$ near or less than 1.0 indicates triggering of soil liquefaction, and $FS_{LIQUEFACTION} > 1.5$ means not liquefiable.

Pseudo-Static Limit Equilibrium Stability Analysis

A pseudo-static analysis is a limit equilibrium method which includes additional seismic inertia forces in a conventional static slope stability analysis. Seismic coefficients (k_h for horizontal and k_v for vertical) are often used in such analysis, and they are normally taken as the peak ground accelerations (PGAs) as a fraction of the gravity acceleration. The seismic inertia forces are represented by $k_h W$ and $k_v W$ in horizontal and vertical direction, respectively, where W is the weight of a sliding block. Due to the nature of seismic shaking, shear strengths of soils for rapid loading conditions are conventionally used for characterization of soil resistance to earthquake loadings.

In a scenario that soils in a dam and its foundation would not develop significant PWP from shaking, a pseudo-static factor of safety greater than 1 (FS-pseudo >1) is a very strong indication that there would be little or no damage to the dam from an earthquake.

However, a pseudo-static factor of safety less than 1 (FS-pseudo <1) does not necessarily represent dam instability or unsatisfactory performance; instead due to the transient nature of earthquake motions, the dam would undergo some deformations for the short time interval when the ground acceleration exceeds the yield acceleration. In such case seismic ground deformations are computed and used for performance assessment.

It is not possible to predict failure of a dam or estimate seismic ground deformations by a pseudo-static analysis, and therefore other types of more comprehensive analysis are required to provide a more reliable basis for seismic design of dams.

Newmark Sliding Block Seismic Deformation Analysis

Newmark (1965) pointed out that for seismic loading permanent ground deformations of a dam, in addition to the pseudo-static factor of

safety, should be considered to be tolerable or not for dam performance assessment. The Newmark deformation method assumes that deformation of a dam is modeled by a rigid block sliding on an assumed failure surface under the design ground motions at the damsite.

Sliding deformation is assumed to occur whenever the acceleration of a sliding block exceeds the yield acceleration, which is the horizontal acceleration that results in a factor of safety of 1 in a pseudo-static slope stability analysis, and the sliding stops when the acceleration falls below the yield acceleration. Mathematically, the Newmark sliding block displacements are computed by double integration of acceleration time history on the sliding block for the portion of accelerations that exceeds the yield acceleration (Fig. 7).

Although it has been widely used at a time when there is lack of direct methods for computing seismic ground deformations, the Newmark sliding block model is generally recognized to be not a very good representation of how embankment dams deform under earthquake, especially for dams with low factors of safety. Due to its simplicity, the method may provide a range of expected ground deformations, but it would neither give distribution of ground displacements in the dam nor provide direct calculation of dam crest settlement.

Post-Earthquake Static Stability Analysis

A direct consequence of soil liquefaction is a great reduction of shear strength, in particular for loose and contractive sands (Fig. 8), for which the shear strength may become a small fraction of its static and drained value due to the buildup of excess pore water pressures and fluidization. In design practice, shear strength of liquefied soil is also described as residual strength and sometime as post-liquefaction strength.

As a frictional material and under static loading, loose sand can have a friction angle possibly ranging from 30° to 35° ; however, the post-liquefaction strength of the same loose sand

Seismic Design of Dams,

Fig. 7 Newmark sliding block deformation calculation diagram

Seismic Design of Dams, Fig. 8 Shear stress – strain response indicating great strength loss after liquefaction and some strength loss with cyclic mobility

may decrease to an equivalent friction angle of 5° or perhaps less (Seed and Harder 1990), indicating the degree of shear strength reduction due to liquefaction.

Residual strength of plastic soils after initial strain softening could decrease to 50–80 % of its pre-earthquake static value, and after sufficient

shaking disturbance, it can eventually decrease to the remolded strength value. Depending on sensitivity, remolded strength of silts and clayey silts may range from about 25 % of its peak static strength for low-sensitivity soils to only 10 % for high-sensitivity soils.

A static limit equilibrium analysis, without seismic loads but using the post-earthquake soil strength, is conducted in order to assess the post-earthquake static stability of the dam. The analysis would use residual strength for liquefied soils and reduced strength in soils that do not liquefy but with the buildup of excess pore water pressures from the design earthquake shaking.

A factor of safety less than 1 from a post-earthquake static stability analysis (FS-post < 1) is a strong indication of dam instability and a potential failure during or immediately after the design earthquake. As such, the design for a new dam would be improved and ground strengthening for an existing dam would be required, in order to increase the post-earthquake dam stability and meet the dam safety requirements.

If $FS_{\text{post}} > 1$ is calculated, ground deformations from the design earthquake are often computed for dam performance evaluation, preferably using a nonlinear finite element dynamic analysis. The Newmark sliding block deformation analysis should be avoided for computing deformations of dams involving soil liquefaction.

Seismic Deformations by Finite Element Dynamic Analysis

A more rigorous and direct method for computing earthquake-induced ground deformations, with and without soil liquefaction, is a nonlinear finite element dynamic analysis (Finn et al. 1994) that overcomes the uncertainties associated with the approximation embedded in the pseudo-static stability calculation and in the Newmark deformation analysis. With PWP calculations built into effective stress soil models, the finite element method has the capability to simulate the coupled effects from dynamic site response, generation of excess pore water pressures, soil liquefaction, and post-liquefaction behavior, and this is a trend method for quantitative evaluation of earthquake-induced ground deformations.

A well-known analysis procedure for the finite element approach is the one developed by Finn et al. (1986) using soil data from centrifuge tests and then verified using soil data and field measured deformations of the Upper San Fernando Dam in California, USA, in a 1971 earthquake (Wu 2001), and recently extended to include a dilative silt model (Finn and Wu 2013). This analysis procedure is highly regarded by practicing engineers and referenced for seismic design of dams by the US Federal Emergency Management Agency (FEMA 2005).

The Finn-Wu finite element procedure is simple and well suitable for practical engineering analysis. This analysis method adopts Mohr-Coulomb criteria for modeling shear strength of soils and uses a nonlinear hyperbolic model to simulate hysteresis response of soils under cyclic

loads. Excess pore water pressures (PWP) caused by earthquake loads can also be computed using effective stress models with calculation of factor of safety against liquefaction for each soil element. In addition, the procedure provides two options for applying input ground motions: (1) ground accelerations applied at the model's rigid base and (2) outcropping ground velocities applied at the model's viscous and elastic base. The elastic base option is often used when the model base stiffness is not rigid relatively to the model body that prevents incident seismic waves from effectively reflecting back to the model body.

As an example of Finn-Wu finite element procedure, factors of safety against liquefaction computed from a dynamic analysis using a subduction earthquake input motion are shown in Fig. 9 (Finn and Wu 2013). The results showed that almost the entire saturated zone (below the water table shown in blue) under the downstream slope of the dam would undergo large cyclic strains with $FS_{\text{LIQUEFACTION}} < 1$. A computed deformed mesh of the dam, with soil material zones shown in colors, immediately after the earthquake using the same subduction ground motion is shown in Fig. 10, indicating a deep-seated ground deformation pattern and significant lateral movement and settlement of the downstream dam crest. The original dam surface is outlined in blue in the figure.

Seismic Performance Evaluation

In some cases, expected performance of dam can be assessed to either clearly safe or clearly unsafe, based on results of simple limit equilibrium stability analyses. In majority cases, however, dam performance is assessed from estimated ground deformations and strains. Ultimately, the expected ground deformations and the associated ground strains, either from a Newmark analysis or a nonlinear finite element analysis, should not exceed what the dam can safely withstand without catastrophic release of the reservoir water due to overtopping or internal

Seismic Design of Dams, Fig. 9 Computed $FS_{LIQUEFACTION}$ shown in colors for an example finite element model of an earthfill dam (undeformed, partial model, dimension in m)

Seismic Design of Dams, Fig. 10 Deformed dam cross section after a subduction earthquake (displacement scale factor 1.0, elevation for vertical axis in m)

erosion. In the process, uncertainties associated with the calculated factor of safety or with the computed ground deformation need to be understood to achieve the confidence on the expected performance. In some cases, the consequences of misjudging uncertainty levels would also be taken into considerations.

Two key factors contributing to uncertainties in predicting the expected performance of dam under earthquake are related to soil liquefaction. The first is “Will liquefaction be triggered?”, and the second is “What is the residual strength after soil liquefaction?” Ideally, a risk analysis would be beneficial to quantify the uncertainties. However, state of practice is mostly based on a deterministic approach for dam performance assessment, such as using analysis steps outlined in Fig. 11.

Overtopping of a dam in earthquake can be caused either by slope instability (failure) or by excess ground deformations (settlement) at dam crest. If post-earthquake stability analyses indicate a factor of safety well above 1 such as $FS_{post} > 1.3$, historical dam performance experience in earthquakes would indicate that the dam will have limited or small deformations and will perform satisfactorily. When liquefaction is not involved, factor of safety greater than 1 with seismic force in a pseudo-static analysis ($FS_{pseudo} > 1$) would also indicate that the dam will perform well in a design earthquake.

On the other hand, confidence in dam safety decreases and probability of a dam failure due to overtopping or internal erosion increases when a post-earthquake factor of safety (FS_{post}) near or less than 1.0 is calculated using residual strengths

Seismic Design of Dams, Fig. 11 Evaluation of dam performance for critical failure modes under earthquake

for liquefied soils. A FS-post less than 1.0 would indicate slope instability under post-earthquake static conditions, and a dam slope failure can occur immediately after the earthquake.

In general, when a wedge or circular sliding surface has a low post-earthquake factor of safety, the deformations along the slip surface would be large or sometime excessive. In these cases, ground deformations calculated preferably from a finite element dynamic analysis are used to assess the potential of a dam failure by overtopping, or internal erosion, or loss of soils in piping.

Engineering judgment is carefully applied in assessing the level of uncertainties in design parameters and analytical methodology and thus the confidence level in the use of calculated deformations. When soil liquefaction is not an issue, deformations estimated from a Newmark sliding block analysis would prove to be adequate for many cases. For dams with liquefaction issues, seismic design or evaluation would use deformations computed from a finite element dynamic analysis, which has adequate soil models for simulation of soil liquefaction and post-liquefaction behavior and also can compute large-strain ground deformations. Even using a finite element approach, computed deformations for dams without involving soil liquefaction would be more reliable (with less uncertainties) than those involving liquefaction.

Summary

This entry describes basic principles and methodology used in seismic analysis and design for earthfill dams.

The risk-based approach for dam safety evaluation is introduced to indicate that seismic design criteria are governed by societal tolerance of seismic risk which consists of both seismic hazard and its consequence. In engineering practice, a full risk analysis is not commonly performed due to its complexity; instead, consequence of a dam failure in an earthquake is often represented using a dam consequence class scheme. A design level of seismic hazards is then selected from the consequence class for a dam. Seismic hazard of a damsite can be evaluated on a probabilistic approach. Once design seismic parameters are determined using the selected seismic hazard level, seismic analysis and design are conducted using a deterministic approach where seismic demands are compared with the ultimate capacity of soils.

State-of-practice methodology for evaluation of soil liquefaction is described, which include measurement of liquefaction resistance of soils by laboratory tests, assessment of liquefaction resistance from in situ tests in the field, soil parameters that impact the liquefaction resistance, and typical values of liquefaction resistance. Liquefaction potential of a soil element is

evaluated by comparing the seismic shear stress from earthquake with the liquefaction resistance of the soil.

Seismic analyses discussed in this entry include pseudo-static stability analysis, Newmark sliding block deformation analysis, post-earthquake static stability analysis, and finite element dynamic analysis for computing permanent ground deformations.

It is pointed out that soil liquefaction is the key factor contributing to uncertainties in predicting the expected performance of dam under earthquake, which are based on results of limit equilibrium stability analyses and in majority cases from estimated ground deformations. Engineering judgment should be applied in assessing the level of uncertainties in design parameters and analytical methodology and thus the confidence level in the use of calculated factors of safety or ground deformations.

Seismic Design of Earth-Retaining Structures

Luigi Callisto

Department of Structural and Geotechnical Engineering, Sapienza Università di Roma, Rome, Italy

Introduction

Earth-retaining structures provide support to excavations or earth fills: the earth pressure is either transmitted to the soil located below the foundations of the structure, as in gravity

retaining walls, or balanced by a combination of horizontal passive forces in the ground and the reaction forces of additional structural elements, as in the case of embedded retaining structures. Seismic forces have a detrimental effect on these structures, producing an increase in the earth pressure and a decrease in the available soil resistance. Commonly, the seismic design of an earth-retaining structure is carried out using a pseudo-static approach, in which the seismic forces are derived from a uniform acceleration field and are applied statically to the soil-structure system. This approach has the advantage of being relatively simple to implement, but the rationale for the choice of the constant acceleration values needs careful consideration. Therefore, the following section provides a simple conceptual model explaining how the pseudo-static acceleration values can be derived from the estimated maximum acceleration and from the acceptable seismic performance of the structure. The remaining sections provide the essential formulas for the evaluation of the seismic earth pressure and deal with specific issues relative to the seismic design of gravity and embedded retaining structures.

Conceptual Model for the Seismic Behavior of Retaining Structures

During an earthquake, the structure and the retained soil are accelerated and are therefore subjected to the corresponding inertial forces that, combining with the preexisting gravitational forces, produce additional loading on the retaining structure. It is important to note that the seismic inertial forces are different from the gravitational forces, as they vary cyclically in amplitude and direction, and have a transient nature. This has important consequences on the seismic design of a retaining structure.

Displacing Retaining Structures

An effective illustration of the seismic behavior of a retaining structure is provided by the simple scheme of a rigid block with a mass m resting on a horizontal base (Fig. 1a). The base is subjected to a simple dynamic excitation, consisting of a horizontal acceleration a_0 that is kept constant over a time interval t_0 , and is then removed (Newmark 1965). If a_b is the block's acceleration, then the corresponding inertial force is ma_b that must be balanced by the resultant force T applied by the

Seismic Design of Earth-Retaining Structures,

Fig. 1 Schematic representation of a rigid block subjected to an acceleration pulse at the base

base to the bottom surface of the block (Fig. 1b). If the capacity at the block-base contact is T_{lim} , then the acceleration of the block cannot be larger than its critical value $a_c = T_{\text{lim}}/m$.

Now suppose that a_0 is larger than a_c (Fig. 1c): since the acceleration of the block cannot go beyond a_c , a relative acceleration occurs between base and block and the corresponding velocity plots tend to diverge, as shown in Fig. 1d. The shaded area between the two velocity plots represents the relative displacement u_r between base and block; if the horizontal acceleration at the base of the block were kept constant at a_0 for a long period of time, the system would be loaded permanently by the inertial forces, and the relative displacement would increase rapidly with an upward concavity. This would be by definition a collapse mechanism: the system capacity is attained under constant forces, and the displacements accelerate.

In the present case, since a_0 is maintained only for the time interval t_0 , it can be seen that as t gets larger than t_0 , the sign of the relative acceleration changes, and the relative velocity decreases. Therefore, the relative displacements increase with a downward concavity and eventually stop when the relative velocity equals zero (Fig. 1e): at the end of this specific event, since the system's capacity has been attained only transiently, the system has not collapsed, but rather suffered a damage in the form of a permanent relative displacement. Whether this damage is acceptable or not depends on the specific function of the system.

This schematic illustration shows that because of the transient nature of the seismic forces, the attainment of the full strength of the system during an earthquake does not imply a collapse, but rather a damage deriving from the temporary activation of a plastic mechanism. In principle, it would be possible to design the structure in such a way that its resistance be never attained during the seismic event ($a_c = T_{\text{lim}}/m > a_0$), but this approach to the design is not particularly desirable, especially for severe, low probability events, because it may be uneconomical and also because the seismic behavior would not benefit

from the dissipation of energy taking place during the activation of the plastic mechanism.

In addition to the inertial forces related to its own mass, a retaining structure is loaded by the earth thrust that in turn increases because the masses of the retained soil are accelerated. Therefore, a scheme more appropriate to a retaining structure is that of Fig. 1f, where the block is loaded additionally by $S_a(a_b)$, which is the resultant force of the total earth pressures corresponding to the acceleration a_b . (Expressions for $S_a(a_b)$ are given in the next section.) Hence in this case a given acceleration produces larger inertial forces. The critical acceleration a_c is derived from the equilibrium equation (Fig. 1g):

$$m a_c + S_a(a_c) = T_{\text{lim}} \quad (1)$$

and is smaller than that of the previous scheme of Fig. 1a: the conceptual model is essentially the same, but from Fig. 1d and e, it is evident that a smaller critical acceleration corresponds to larger relative velocities and hence to larger displacements.

The schematic model of Fig. 1 evidences an important principle: since the block's acceleration cannot exceed a_c , the internal forces acting within the block cannot go beyond those evaluated for $a = a_c$. Since a_c is related to the seismic resistance of the system, it follows that stronger systems are called to resist larger internal forces.

With reference to the seismic design of a retaining structure, one can depict two different cases:

1. The critical acceleration of the system a_c is larger than the maximum acceleration at the base a_0 ; in this case, the maximum acceleration of the block is a_0 , there are no relative displacements, and the maximum internal forces are evaluated with $a = a_0$.
2. The critical acceleration of the system a_c is smaller than the maximum acceleration at the base a_0 ; in this second case, the maximum acceleration of the block is a_c ; the

displacements increase as a_c decreases; the internal forces are evaluated with $a = a_c$ and increase with a_c .

This conceptual model can be used to illustrate a performance-based approach to the design of earth-retaining structures. A given limit state corresponds to a certain design seismic action that must be found accounting for the local site response. The required seismic performance of a retaining structure can be expressed by its permanent displacement and can be chosen by the designer for compatibility with the limit state under consideration. The design consists on one hand in endowing the system with a critical acceleration sufficiently large to produce displacements that do not exceed the specified limit and on the other hand in protecting the structural elements from a premature yielding by making sure that their structural capacity is sufficient to carry the maximum internal forces occurring during the development of the displacements.

Evaluation of Seismic Displacements

The conceptual model of Fig. 1 can be used directly to evaluate, for a given acceleration time history at the base, the seismic displacements of a retaining structure. This is accomplished as shown in Fig. 2: whenever the base acceleration $a(t)$ exceeds a_c , the time history of the relative acceleration $a(t) - a_c$ is integrated to provide the relative velocity v_r . The integration is halted when v_r equals zero and is restarted when $a(t)$ becomes again larger than a_c . It is recognized that a retaining wall can move only downhill; therefore, the positive and the negative portions of the acceleration time histories are considered one at a time. The displacements are obtained from the integration of the time history of the relative velocity.

The direct evaluation of the displacements depicted in Fig. 2 is very simple, but can be performed only if the seismic action is described as a set of accelerograms. This implies the evaluation of the outcrop seismic motion that must be inserted into a detailed site response calculation, which in turn requires an accurate geotechnical

Seismic Design of Earth-Retaining Structures, Fig. 2 Illustration of the Newmark (1965) integration scheme

characterization of the soil deposits, starting from the bedrock.

For simple earth-retaining structures, the outcrop seismic action is more commonly expressed as an elastic response spectrum, and the local site response is considered through simple amplification coefficients, usually based on the classification of the subsoil according to the shear wave velocity of the topmost, say, 30 m. In this case, acceleration time histories are not available: a direct calculation of the displacements is not possible, and it is necessary to use a simplified approach.

The final displacement induced by the acceleration time history of Fig. 1 can be evaluated as

$$u_r = \frac{v_0^2}{2a_c} \left(1 - \frac{a_c}{a_0} \right) \quad (2)$$

where $v_0 = a_0 t_0$ is the maximum acceleration at the base. Newmark (1965) argued that a given acceleration time history can be approximated as $a_{\max}/a_c$ cycles equivalent to the simple impulse of Fig. 1, where $a_{\max}$ is the maximum recorded acceleration. This assumption results in the following expression for the final displacement:

Seismic Design of Earth-Retaining Structures,
Fig. 3 Seismic displacements plotted as a function of
 the critical to maximum acceleration ratio

$$u_r = \frac{v_{\max}^2}{2a_c} \left(1 - \frac{a_c}{a_{\max}}\right) \cdot \left(\frac{a_{\max}}{a_c}\right) \quad (3)$$

where $v_{\max}$ is the maximum recorded acceleration.

Franklin and Chang (1977) selected a number of accelerograms scaled to $a_{\max} = 0.5 \text{ g}$ and $v_{\max} = 0.76 \text{ m/s}$; they produced a parametric integration of these accelerograms for different values of the ratio $a_c/a_{\max}$. Richards and Elms (1979), based on the same acceleration time histories, produced the following relationship for the prediction of the seismic displacements:

$$u_r = 0.087 \frac{v_{\max}^2}{a_{\max}} \cdot \left(\frac{a_{\max}}{a_c}\right)^4 \quad (4)$$

The displacements predicted by the above relationships are plotted in Fig. 3 as a function of the ratio $a_c/a_{\max}$, together with the results by Franklin and Chang (1977) and with the curves proposed by Wong (1982) for the average values and by Whitman (1990) for the values associated to a 95 % confidence. In principle, the use of the

previous relationships or of the diagram of Fig. 3 is quite immediate; the critical acceleration expresses the resistance of the retaining structure to the seismic action and can be evaluated using the earth pressure formulas given in the following; $a_{\max}$ is the maximum expected acceleration for the limit state under consideration; the maximum velocity $v_{\max}$ can be estimated, for instance, from the constant-velocity portion of the elastic spectra provided by the construction codes (e.g., EN 1998-5 2003).

However, Fig. 3 shows that for a given ratio $a_c/a_{\max}$, the available relationships result in a very large uncertainty for the displacement. The reason for this substantial scatter is that the maximum recorded acceleration alone is not sufficient to represent the characteristics of an accelerogram. While in principle it is possible to produce more accurate expressions that relate the displacements to additional properties of the seismic motion (frequency content, Arias intensity, duration, etc.), often the designer that wishes to adopt a simplified procedure is provided only with an estimate of $a_{\max}$. An alternative way to obtain a more accurate prediction of the seismic displacement is to use the structure of the above predictive equations for the development of local relationships based on regional seismic records.

Equivalent Seismic Action on Retaining Structures

Consider a relationship between the displacement u_r and the ratio $a_c/a_{\max}$ that can be deemed appropriate to the local seismicity (Fig. 4). If u_0 is the tolerable displacement for the limit state under consideration and β is the corresponding value of the ratio $a_c/a_{\max}$, then the requisite that $u \leq u_r$ implies that the critical acceleration a_c must be larger than $\beta a_{\max}$ (with $\beta < 1$). This means that a check that the desired performance is met can also be done by controlling that under the conventional seismic forces associated to the acceleration $\beta a_{\max}$, the resistance of the system is not exceeded.

In other words, the performance of the retaining structure that in principle should be evaluated in terms of displacements can also be checked in terms of equivalent forces. This is

Seismic Design of Earth-Retaining Structures, Fig. 4 Relationship between seismic displacements and the ratio $a_c/a_{\max}$ developed by Rampello et al. (2010) for stiff soils based on the Italian seismicity

commonly expressed in terms of seismic coefficients: seismic forces deriving from a horizontal seismic coefficient,

$$k_h = \beta a_{\max}/g, \quad (5)$$

generally used in conjunction with a vertical seismic coefficient expressed as a fraction of k_h , must be such that the system capacity is not exceeded.

Note that no global or partial safety coefficient should be used in this check, as this is not an assessment of the safety with respect to a collapse mechanism, but rather an indirect evaluation of the seismic performance of the system.

Non-displacing Retaining Structures

In some circumstances, a retaining structure cannot undergo permanent deformation resulting from the activation of a plastic mechanism. This may be due either to the design requirements for the specific limit state implying a negligible damage to the structure or to the retaining structure being significantly constrained by additional structural elements, like props, rakers, etc.

In the absence of displacements, the coefficient β of Eq. 5 is equal to 1, and therefore the seismic earth pressure can be evaluated using the formulas given in the following section, using a horizontal seismic coefficient corresponding to the maximum acceleration. However, there are cases in which a different approach is necessary, and the soil should be regarded as an elastic material. These are dealt with at the end of the next section.

Evaluation of Earth Pressure

Earth Pressure in Active and Passive Limit States

When a plastic mechanism is mobilized, forces and/or stresses transmitted by the soil in contact with the retaining structure may be evaluated by assuming that the soil is in limit conditions, that is, its shear strength is completely mobilized. If the retaining structure displaces away from the soil, the soil is in an active limit condition; conversely, if the soil is contrasting the displacement of the retaining structure, it is in a passive limit condition.

For a purely frictional strength criterion, the resultant force applied by the soil to the retaining structure may be found using the Mononobe-Okabe approach (Okabe 1924; Mononobe and Matsuo 1929), which is an extension to seismic conditions of the Coulomb's limit equilibrium method. In active limit conditions, the total earth thrust S_{aE} is provided by a volume of soil that slides downward along a planar surface with an inclination α to the horizontal; this mechanism is shown in Fig. 5, where φ is the angle of shearing resistance of the soil and δ is the angle of friction at the soil-structure contact. The earth thrust is found by maximizing with respect to α the force that ensures the translational equilibrium for the soil wedge of Fig. 5, subjected to the bulk force W_E and to the resultant force R applied by the in situ soil onto the sliding plane. Since the shear strength of the soil is fully mobilized along the sliding surface, R is inclined by φ with respect to the normal to the

Seismic Design of Earth-Retaining Structures,

Fig. 5 Illustration of the Mononobe-Okabe approach for the evaluation of the active seismic force on a retaining structure

sliding plane and S_{aE} has an inclination δ with respect to the normal to the retaining structure. The seismic forces are included in the analysis by considering the horizontal and vertical seismic coefficients k_h and k_v in the evaluation of W_E .

The value of S_{aE} , maximized with respect to α , is given by the expression

$$S_{aE} = \frac{1}{2} \gamma \cdot (1 - k_v) \cdot H^2 \cdot K_{aE} \quad (6)$$

where γ is the soil unit weight, H is the height of the retaining structure, and K_{aE} is the coefficient of active thrust, evaluated with the following equation:

$$K_{aE} = \frac{\cos^2(\varphi - \beta - \theta)}{\cos \theta \cos^2 \beta \cos(\delta + \beta + \theta) \left[1 + \sqrt{\frac{\sin(\varphi + \delta) \sin(\varphi - \varepsilon - \theta)}{\cos(\delta + \beta + \theta) \cos(\varepsilon - \beta)}} \right]^2} \quad (7)$$

in which the angles β and ε have the meaning depicted in Fig. 5 while the angle θ defines the direction of W_E :

$$\theta = \arctan \frac{k_h}{1 - k_v} \quad (8)$$

The inclination α_{cr} of the sliding surface that maximizes S_{aE} can be evaluated with the following expression:

$$\alpha_{cr} = (\varphi - \theta) + \arctan \left[\frac{\{\tan a (\tan a + \cot b) [1 + \tan(\delta + \beta + \theta) \cot b]\}^{\frac{1}{2}} - \tan a}{1 + \tan(\delta + \beta + \theta) (\tan a + \cot b)} \right] \quad (9)$$

with

$$\begin{aligned} a &= \varphi - \varepsilon - \theta \\ b &= \varphi - \beta - \theta \end{aligned} \quad (10)$$

The active pressure S_{aE} given by Eq. 6 is a function of the horizontal acceleration, through

the dependency of K_{aE} on k_h (Eqs. 7 and 8); therefore, it can be regarded as the function $S_a(a_b)$ introduced in the previous section and used accordingly.

Equations 6, 7, and 8 imply quite obviously that S_{aE} increases with the horizontal seismic coefficient k_h . Conversely, it can be seen from

Eqs. 9 and 10 that the angle α_{cr} decreases with k_h , implying that the dimensions of the sliding wedge increase with the earthquake intensity. In other words, for larger accelerations, the volume of soil that interacts with the retaining structure is larger, and this finding has several implications, for instance, in the selection of the relevant strength parameters or for the design of a drainage system that needs to be effective in controlling the pore pressure within the entire volume of soil interacting with a retaining wall.

Since the Mononobe-Okabe method considers only translational equilibrium, it provides no direct information on the point of application of S_{aE} .

For passive limit conditions, the Mononobe-Okabe approach is not recommended, because

the assumption of a planar sliding surface is not conservative, especially when the soil-wall frictional coefficient δ approaches φ .

A more general approach to evaluate the seismic pressure in active and passive limit conditions is to use the lower-bound theorem of limit analysis. A convenient expression for vertical walls was derived by Lancellotta (2007) for passive limit conditions and extended by Rampello et al. (2011) to active limit conditions. The effective normal stress acting on the retaining structure in active or passive limit conditions $\sigma'_{a,p}$ is expressed as the product of a suitable thrust coefficient $K_{a,p}$ and the notional vertical effective stress σ'_v ; the thrust coefficient has the expression

$$K_{a,p} = \left[\frac{\cos \delta}{\cos(\varepsilon - \theta) \pm \sqrt{\sin^2 \varphi - \sin^2(\varepsilon - \theta)}} \cdot \left(\cos \delta \mp \sqrt{\sin^2 \varphi - \sin^2 \delta} \right) \right] \frac{\cos \varepsilon}{\cos \theta} (1 - k_v) \cdot e^{\mp 2\psi \tan \varphi} \quad (11)$$

with

$$\psi = 0.5 \left\{ \arcsin \left(\frac{\sin \delta}{\sin \varphi} \right) \mp \arcsin \left[\frac{\sin(\varepsilon - \theta)}{\sin \varphi} \right] \mp \delta + (\varepsilon - \theta) + 2\theta \right\} \quad (12)$$

In the above expressions, the upper and lower operators apply to active and passive conditions, respectively. Equations 11 and 12 imply that K_a increases and K_p decreases with θ , that is, with the seismic acceleration.

Providing normal stresses that are proportional to the vertical effective stresses, this lower-bound solution yields the entire distribution of soil-wall contact stresses that can be used to study the equilibrium of the retaining structure for the selected limit state.

Effect of Pore Water Pressure

The presence of pore water pressures produces a change in the seismic contact stresses. This effect

is better evaluated using the above lower-bound solution. The total contact stress $\sigma_{a,p}$ is equal to the sum of the effective contact stress $\sigma'_{a,p}$ and the pore pressure u :

$$\sigma_{a,p} = K_{a,p} \sigma'_v + u = K_{a,p} (\sigma_v - u) + u \quad (13)$$

The change in total contact stresses $\sigma_{a,p}$ is not caused only by the introduction of u in the above expression but also by the coefficients of earth pressure in seismic condition depending on the pore water pressure.

For most practical purposes, it can be assumed that during the seismic motion, the pore water vibrates in phase with the soil skeleton (Matsuzawa et al. 1984 suggest that this is the case for permeability coefficients smaller than 10^{-5} m/s). The evaluation of the seismic pressure should consider that the inertial forces in the soil are proportional to the total mass of the soil skeleton and the pore water while the shear strength is proportional to the effective stresses. Callisto and Aversa (2008) showed that this

effect can be taken into account by modifying the expression of θ in Eq. 8, which becomes

$$\theta' = \arctan\left(\frac{\sigma_v}{\sigma'_v} \frac{k_h}{1 - k_v}\right) \quad (14)$$

where σ_v is the total vertical stress. This expression leads to larger values of K_a and to smaller values of K_p , showing that pore water pressures have a detrimental effect on the coefficients of earth pressure. Expression (14) implies that K_a and K_p may vary with depth even in a homogeneous soil. For the particular, and quite uncommon, case of a hydrostatic pore water pressure distribution with the total hydraulic head at the ground surface, expression (14) becomes independent of depth:

$$\theta' = \arctan\left(\frac{\gamma}{\gamma'} \frac{k_h}{1 - k_v}\right) \quad (15)$$

where γ is the unit weight and γ' is the submerged weight of the soil. Use of expression (15) is explicitly suggested by Eurocode 8 part 5 (EN 1998-5 2003).

Effect of Cohesion

The relationships listed above were developed for a purely frictional material. For some of these solutions, the possibility exists to account rigorously for the effect of cohesion. However, small values of the cohesion c' can be incorporated in the analysis with sufficient accuracy using the Rankine expression:

$$\sigma'_{a,p} = \mp 2c' \sqrt{K_{a,p}} + K_{a,p} \sigma'_v \quad (16)$$

Drainage Conditions

For a saturated soil, it can be assumed that the seismic event occurs in undrained conditions, even for coarse-grained materials. The excess pore water pressures Δu generated during the earthquake can be easily incorporated into Eq. 13, to provide (for a purely friction material)

$$\sigma_{a,p} = K_{a,p} [\sigma_v - (u + \Delta u)] + (u + \Delta u) \quad (17)$$

If a wall retains an excavation in a fine-grained soil, in the long-term, the removal of soil produces a significant over-consolidation and the volumetric response of the soil becomes dilatant. In this case, the seismic event is likely to produce a decrease of the pore water pressures ($\Delta u < 0$), and this beneficial effect may be neglected. However, for relatively loose coarse-grained soils, the earthquake may produce a significant increase Δu of the pore water pressure. The evaluation of Δu for coarse-grained material is beyond the scope of this entry; the reader may refer to the sections devoted to liquefaction and to Seed and Booker (1977).

An excavation in fine-grained material can be taken to occur in approximately undrained conditions, generating negative excess pore water pressures. Traditionally, the static design of an excavation in these conditions is carried out expressing the shear strength of the soil in terms of total stresses, using the Tresca criterion and a limiting shear stress equal to the undrained shear strength S_u . Yet for the analysis of the seismic conditions, a total stress analysis is seldom appropriate, because the time interval corresponding to a significant dissipation of the excess pore water pressure may be considered to be much smaller than the return period of any severe seismic event. Therefore, the seismic design is controlled by the seismic events that, having a large return period (e.g., 475 years for a 10 % probability over a life span of 50 years), may be deemed to produce effects on a retaining structure that is already in drained conditions.

Evaluation of Earth Pressure for Non-displacing Retaining Structures

Although the case of zero displacement can be addressed simply by inserting $\beta = 1$ into Eq. 5 and therefore evaluating the earth pressure using the maximum predicted acceleration, there are cases in which active limit conditions may not develop at the rear of a retaining structure, because of the very small deformation allowed during the excavation or because the wall has been backfilled after its construction. In these situations, if the deformation of the retaining structure is impeded during the seismic event, a

different approach is in order to evaluate the earth pressure, based on the hypothesis that the soil does not attain its strength and can be modeled as a linearly elastic material. The increase in the horizontal stress produced by the earthquake can then be expressed as

$$\Delta\sigma_{hE} = \gamma H \frac{a_{\max}}{g} \cdot f \quad (18)$$

where H is the height of the retaining structure. For an infinitely rigid wall, the coefficient f may be taken equal to 1 (Wood 1973). For a flexible wall, the coefficient f is a function of the soil-wall relative stiffness d_p , expressed as (Younan and Veletsos 2000)

$$d_p = \frac{G_s H^3}{(EI)_w} \quad (19)$$

In the above relationship, G_s is the shear modulus of the backfill, and the quantity $(EI)_w$ is the bending stiffness of the retaining structure (per out-of-plane length). Figure 6 shows the coefficient f plotted as a function of the relative stiffness d_p as obtained by Younan and Veletsos (2000) for two different restraining conditions. This graph,

Seismic Design of Earth-Retaining Structures,
Fig. 6 Coefficient f of Eq. 18 plotted as a function of the relative stiffness d_p

together with Eqs. 18 and 19, may be used to evaluate the design earth pressures.

Gravity Retaining Walls

In static conditions, gravity retaining walls transfer the sub-horizontal earth thrust S to the foundation soil, thanks to their considerable self-weight. Figure 7 shows that the weight of the wall W combines with S to yield a resultant force R that (i) goes through the base of the wall and (ii) has a small inclination to the vertical. As shown in Fig. 7, different types of gravity retaining walls have a similar global behavior, the only difference being the relative amount of soil contributing to the total weight of the structure.

Since these structures are endowed with a significant mass, seismic accelerations produce large inertial forces that must be taken into account, considering both the horizontal and vertical acceleration components.

Construction codes provide the values of the seismic coefficient that should be used for the design, essentially in the form of the reduction coefficient β of Eq. 5, depending on the allowable displacement at the end of the earthquake. Using the appropriate seismic coefficient, the design of a gravity retaining wall is carried out studying global and local mechanisms. The global mechanisms are essentially the same for the different types of retaining structures depicted in Fig. 7: (a) sliding along the base, (b) bearing capacity of the foundation, (c) overturning, and (d) overall slip-circle mechanism (Fig. 8). Local mechanisms are relative to the attainment of the structural strength or to the mobilization of the reinforcement strength in a reinforced earth structure.

The details of each safety check are given by the construction codes and therefore are not dealt with here. However, a general appreciation of the seismic design of a retaining wall is provided by the example of Fig. 9, relative to a cantilever retaining wall with a height $H = 3.5$ m subjected to a seismic event characterized by a maximum acceleration $a_{\max} = 0.25$ g. Restricting the

Seismic Design of Earth-Retaining Structures, Fig. 7 Transfer of earth pressure to the foundation soils for gravity retaining walls

Seismic Design of Earth-Retaining Structures, Fig. 8 Global limit states for a gravity retaining wall

attention to the sliding mechanism only, Fig. 9 shows the values of the critical acceleration a_c plotted as a function of the width B of the wall base and of the corresponding displacements evaluated using the relationship of Fig. 4. It is evident that wider walls have a larger critical acceleration and therefore undergo smaller displacements. The figure also shows the maximum bending moment $M(a_c)$ in the wall stem, evaluated when the wall is critically accelerated. It is evident that since the bending moments increase with a_c , they must show an increasing trend with B . Hence, if a retaining wall is designed

with a large base to have a particularly good seismic performance, it must be endowed with a correspondingly large structural strength to resist the internal forces associated with its large critical acceleration. Following this line of thought, it is evident that a wall with a critical acceleration equal to $a_{\max}$ will suffer negligible displacement and will be subjected to internal forces that cannot be larger than those evaluated with an acceleration equal to $a_{\max}$.

It should be noted that any “safe” provision, such as the use of strength or resistance factors, or an underestimation of the soil strength, leads to

Seismic Design of Earth-Retaining Structures, Fig. 9 (a) Example of a retaining wall; (b) critical acceleration, displacement, and maximum bending moment plotted as a function of base width

Seismic Design of Earth-Retaining Structures, Fig. 10

Reference schemes of a cantilevered (a) and a singly propped (b) embedded retaining wall, showing the direction of the inertial forces activating the plastic mechanisms

design acceleration smaller than the critical one. Figure 9 shows clearly that a larger critical acceleration implies on one hand smaller displacements and on the other hand larger internal forces. For the structural design of the wall, it is then recommendable to evaluate always the internal forces corresponding to the actual critical acceleration of the wall.

Embedded Retaining Walls

The seismic behavior of embedded retaining walls is different from that of gravity retaining walls, in that the earth thrust is resisted by the passive strength of the soil in front of the wall and by additional constraints (anchors, props); therefore, it is not necessary that the structure

possesses a large mass and the corresponding inertial forces are small; the effect of vertical acceleration can usually be neglected.

On the other hand, cantilevered or singly propped walls (Fig. 10) bear some similarities with gravity retaining walls, because if the strength of the soil interacting with the wall is attained during the seismic event, a plastic mechanism may develop, and the earth pressure relationships may be used in a limit equilibrium computation to evaluate the critical acceleration that activates the mechanisms. Figure 11 shows an example in which a cantilevered retaining wall is subjected to a maximum acceleration $a_{\max} = 0.5$ g. For this wall, the critical acceleration can be obtained studying the rotational mechanism of Fig. 10 using, for instance, the Lancellotta (2007) closed form expressions for

Seismic Design of Earth-Retaining Structures, Fig. 11 (a) Example of an embedded retaining wall; (b) critical acceleration, displacement, and maximum bending moment plotted as a function of embedded length

the active and passive pressures. The results are very similar to those developed for the example retaining wall of Fig. 9, showing that increasing the embedded length of the wall the critical acceleration increases, and therefore the permanent displacement decreases but the internal forces in the wall become larger. For these wall types, it is recommended that the internal forces be evaluated considering the critical value of the acceleration, that is, considering the activation of the plastic mechanisms depicted in Fig. 10.

When the structure has several additional constraints, the attainment of the soil strength is not sufficient for the activation of a plastic mechanism: if the design requires that the capacity of the wall itself and of the constraints cannot be reached, then these should be classified as a non-displacing wall and the earth pressure should be evaluated accordingly, as explained in a preceding section. In this perspective, no consideration of plastic mechanisms is needed, and the objective of the design is essentially the evaluation of the maximum internal forces in the structural members that should derive necessarily from a study of the soil-structure interaction.

However, the analysis of the soil-structure interaction under seismic conditions is not straightforward and can be carried out at different levels of complexity. A very basic representation of the soil-structure interaction is represented by the subgrade reaction methods that constitute a

standard method for the static design of multi-constrained retaining wall (Fig. 12a). While there is not a general consensus on the use of this method in seismic conditions, a simple strategy for taking into account the inertial force consists of the following steps:

- (i) Carry out a static analysis to model the construction sequence (Fig. 12b).
- (ii) Evaluate the additional forces due to the earthquake and the reduction of the coefficient of passive resistance, as a function of the maximum acceleration estimated for the site.
- (iii) Apply these forces as external loads on the subgrade reaction model, and reduce the coefficient of passive resistance (Fig. 12c).
- (iv) Run the program for equilibrium and compatibility (Fig. 12d).

Summary

The current trend in the design of earthquake-resistant structures is based on the evaluation of the seismic performance of the system. For a retaining structure, the seismic performance is expressed by its cumulative displacement at the end of the earthquake. Although it would be desirable to evaluate directly the performance of the structure, it has been shown that a design

Seismic Design of Earth-Retaining Structures, Fig. 12 Use of a subgrade reaction model for the seismic analysis of a multi-propped retaining wall

requirement limiting the seismic displacements can be transformed into an equivalent requirement on the seismic action that needs to be considered in a conventional design process, which is commonly based on forces. Specifically, the conventional seismic coefficient used in a pseudo-static calculation can be made to decrease as the allowable displacement decreases. Specific cases of non-displacing walls have been evidenced that may call for a different approach, in which the internal forces are evaluated assuming that the soil does not mobilize its strength during the earthquake.

Introduction

Pipelines are a cost-effective means for the transportation of water supply and sewers, in addition to commercial fluids such as oil and gas. The designation of pipeline systems as “lifelines” indicates that they should be designed to function and operate at all times for public safety and well-being and also for economic reasons. Engineers must consider the different types of loads that are going to be imposed on the pipeline, the environment that the pipeline will travel in, and the type of material that the pipeline is going to convey. Consequently, pipelines must be designed for different loads such as stresses due to pressure generated by the flow (internal pressure), external pressure generated by the weight of earth and by live loads for buried pipelines, or external pressure generated by fluid if the pipe is submerged underwater. Also, seismic loads (earthquake loads) in medium and high seismicity zones are detrimental and should be considered. In general, pipeline design includes several general steps: (1) load determination, (2) critical performance evaluation (determining the critical stress and/or deformation), (3) comparison of the critical performance with the limiting criteria established by adopted codes and standards, and finally (4) selection of the pipe.

Over the past century, several catastrophic earthquakes caused severe damage to buried pipelines. In the 1906 San Francisco earthquake, one of the main reasons that caused the extensive damage was due to the failure of several water

pipelines which hindered firefighting efforts. Several years later, in the 1971 San Fernando earthquake, about 80 % of the reported destruction were in welded steel buried pipelines. Following the 1989 Loma Prieta earthquake, the East Bay Municipal Utilities District identified over 120 water pipeline breaks, and the San Jose Water Company reported another 155 pipe breaks. However, most of the serious damage reported by Pacific Gas and Electric Company (PG&E) occurred to natural gas mains and service lines. During the Northridge earthquake (1994) in California, some natural gas pipelines were severely damaged and the leak of containment fluid caused a large explosion in the Northridge town resulted in several deaths (Lau et al. 1995; O'Rourke and Palmer 1996). In the 1995 Hyogo-Ken Nanbu earthquake (in Japan), the natural gas leakage from buried pipelines resulted in numerous number of fires (531 cases reported) which started primarily due to gas release and electricity sparks affecting areas of over one square kilometer totally burnt (Scawthorn and Yanev 1995). More recently, the 1999 Chi-Chi earthquake (in Taiwan) also caused severe damage to natural gas distribution systems. More than 100,000 customers were affected after the earthquake, and the estimated economic loss of five major natural gas companies was approximately US\$ 25 million (Chen et al. 2000). In the 1999 Izmit earthquake (in Turkey), Tupras refinery suffered serious fire damage as the pipeline conveying water from neighbor lake was damaged, so the refinery was dependent on internal water reservoirs which were insufficient. In 2001 two earthquakes occurred (1 month apart) in San Salvador; several pipelines in rural areas experienced severe destruction caused by huge landslides. Till now, in several very recent earthquakes occurred in Chile (2010), New Zealand (Darfield, 2010), Japan (Tohoku, 2011), and Italy (earthquake of Emilia, 2012), serious damages to pipelines have been witnessed.

Accordingly, pipelines should be designed to function and operate during and following design earthquakes for life safety and economic reasons. As mentioned above several earthquakes in the

Seismic Design of Pipelines, Fig. 1 Main types of faults

last few decades resulted in too many pipeline breakings, and that extensive pipe breakage has the potential to lead to great economic harm to our urban communities.

The main focus of this chapter will be centered on the seismic analysis and design of pipelines.

Permanent Ground Deformation and Seismic Wave Propagation Hazards

In seismic events, buried pipelines can be damaged mainly by either the permanent ground deformations (PGD) or by the transient seismic wave propagation. PGD movements include faulting, landslides, lateral spreading due to liquefaction, and seismic settlement. Even though PGD risks are usually restricted to small regions within the pipeline, the chances of them causing severe damage is substantial since they impose large deformations. On the other hand, the seismic wave propagation risks typically affect the whole pipeline, but with lower damage rates (as the total deformations are general less and not permanent). For example, only 5 % of the affected area experienced lateral spreading during the 1906 San Francisco earthquake; approximately 52 % of all pipeline breaks occurred within one city block of the lateral spreading (O'Rourke et al. 1985).

Permanent Ground Deformation (PGD)

This section describes in details the four different forms of permanent ground deformation and

presents methods to calculate the amount of PGD as well as the extent of the PGD zone. Equations to quantify the amount of PGD are provided. Also, useful observations and notes to determine the extent of the PGD zone are presented and discussed.

Fault

Stresses in the earth's crust push the two sides of the fault. Eventually enough stress builds up and the rocks slip suddenly releasing energy in waves that travel through the rock to cause earthquake. Accordingly, earthquakes occur on faults. A fault is a thin zone of crushed rock separating blocks of the earth's crust. When an earthquake occurs on one of these faults, the rock on one side of the fault slips with respect to the other. The fault surface can be vertical, horizontal, or oblique to the surface of the earth. If the earthquake magnitude is large enough, the offset along the fault will propagate all the way to the earth's surface causing surface rupture (fault offset). Figure 1 below shows the main types of faults. In normal and reverse faults, the major ground displacement is vertical with a minor horizontal displacement. These ground displacements pose axial tension/compression and bending stresses in the pipeline depending on the direction of movement. On the other hand, in strike slip fault the main deformation (the offset) occurs in the horizontal plane, which poses axial tension/compression and bending stresses in the pipeline depending on the intersection angle of the pipeline and the fault.

The following empirical equations by Wells and Coppersmith (1994) are the most recognized equations to estimate the average fault displacement relative to the size of the considered earthquake:

$$\text{For the normal fault} \rightarrow \log \delta_f = -4.45 + 0.63 M \quad (1)$$

$$\text{For the reverse fault} \rightarrow \log \delta_f = -0.74 + 0.08 M \quad (2)$$

$$\text{For the strike slip fault} \rightarrow \log \delta_f = -6.32 + 0.90 M \quad (3)$$

where δ_f is the average fault displacement in meters and M is the moment magnitude of the earthquake.

Landslides

Seismically induced landslide involves a wide range of downslope mass ground movements, which can occur in offshore, coastal, and onshore environments.

Offshore Landslides In offshore landslides, the response of the pipeline is mainly governed by the orientation of the pipeline to the direction of ground movement. The imposed displacements for undersea slides are so large that pipeline response is likely controlled by the maximum force available at the soil-pipe interface.

Onshore Landslides There are several types of onshore landslides based on soil movements, geometry of the slide, and the types of material involved. The main types are rock falls, rock topples, slides, and lateral spreads. Rock fall and rock topple can cause direct damage to above-ground pipelines by the impact of falling rock fragments. In an earth slide the earth moves relatively as a block; they typically develop along natural slopes and embankments.

Based on Newmark's Block model for landslides (Newmark 1965), the critical acceleration at which the slide will be triggered α_c can then be determined from

$$a_c = g (\text{FOS} - 1) \sin \alpha \quad (4)$$

where g is the acceleration due to gravity, FOS is the factor of safety, and α is the angle of the slope.

Then the displacement of the block can be calculated by double integrating the ground acceleration. Jibson and Keefer (1993) proposed the following equation to estimate the Newmark displacement, δ_s , in centimeters as

$$\text{Log } \delta_s = 1.460 \log I_a - 6.642 a_c + 1.546 \quad (5)$$

where α_c is the critical acceleration in g s and I_a is the Arias Intensity in m/s .

Arias Intensity can be calculated using the following relationship developed by Wilson and Keefer (1983):

$$\text{Log } I_a = M - 2 \log R - 4.1 \quad (6)$$

where M is the earthquake magnitude and R is source distance in kilometers.

Lateral Spreading Due to Liquefaction

Seismic shaking may trigger the liquefaction of saturated loose cohesionless soils. The liquefaction process increases the pore water pressure in the ground to a level where the effective stress approaches zero at which point the soil loses entirely its shear strength, which in turn results in the lateral movement of the soil (lateral spreading). In past major earthquakes, large number of pipelines suffered massive damage caused by liquefaction-induced ground failures (Zhang et al. 2004).

Youd et al. (2002) proposed two empirical equations to approximately estimate the PGD due to liquefaction:

For lateral spreads down gentle ground slopes (GS),

$$\begin{aligned} \text{Log } \delta_L = & -16.213 + 1.532 M - 1.406 \log R^* \\ & - 0.012 R + 0.338 \log S + 0.54 \log T_{15} \\ & + 3.413 \log (100 - F_{15}) \\ & - 0.795 \log (D50_{15} - 0.1) \end{aligned} \quad (7)$$

Seismic Design of Pipelines, Fig. 2 Sketch showing the ground slope and the free face lateral spreads

For lateral spreads at a free face (FF),

$$\begin{aligned} \log \delta_L = & -16.710 + 1.532M - 1.406 \log R^* \\ & - 0.012R + 0.592 \log Y + 0.54 \log T_{15} \\ & + 3.413 \log(100 - F_{15}) \\ & - 0.795 \log(D50_{15} - 0.1) \end{aligned} \quad (8)$$

where δ_L is the PGD in meters, M is the earthquake magnitude, S is the ground slope %, γ is the free face ratio (in % see Fig. 2), T_{15} is the thickness in meters of the saturated cohesionless soil layer with a corrected standard penetration test (SPT value of less than 15), F_{15} is the percentage of average fines contents in T_{15} (in %), $D50_{15}$ is the mean grain size in mm in T_{15} , and R^* is an adjusted distance parameter in kilometers given by

$$R^* = R + 10 e^{(0.89M - 5.64)} \quad (9)$$

where R is the horizontal distance in kilometers from the site of interest to the nearest bound of the seismic energy source (do not use less than 0.5 km).

Seismic Settlement

Seismic-induced settlement may be caused by densification of cohesionless soils, consolidation of cohesive soils, or consolidation of liquefied soil. In this section we will only discuss liquefaction-induced ground settlement as it can cause larger settlement and hence higher potential for damage to buried pipelines.

Takada and Tanabe (1988) proposed the two following empirical equations to calculate liquefaction-induced settlement at embankments and leveled sites:

For embankments

$$\delta_{GS} = 0.11 H_1 H_2 \frac{a_{\max}}{N} + 20 \quad (10)$$

For leveled sites

$$\delta_{GS} = 0.30 H_1 \frac{a_{\max}}{N} + 2 \quad (11)$$

where δ_{GS} is the liquefaction-induced settlement in centimeters, H_1 is the thickness of saturated cohesionless soil layer in meters, H_2 is the height of embankment in meters, N is the SPT N -value in the cohesionless layer, and $a_{\max}$ is the ground acceleration in gals.

Seismic Wave Propagation

For the seismic analysis and design of buried pipelines, the effect of the seismic wave propagation on the pipeline is usually characterized by the induced ground strain and curvature. Newmark (1967) developed a straightforward method to estimate the ground strain. The general form of a traveling wave in Newmark's method is given by

$$U = f \left(\frac{t}{T} + \frac{x}{\lambda} \right) \quad (12)$$

where U is the function of the separation distance between the two points, x , and the speed of the seismic wave; T is the period of the repeating motion; and λ is the wavelength.

For particle motion parallel to the direction of propagation (R-waves), ϵ_g , the ground strain along the direction of propagation can be calculated as

$$\epsilon_g = \frac{V_{\max}}{C_R} \quad (13)$$

where $V_{\max}$ is the maximum horizontal ground velocity in the direction of wave propagation and C_R is the propagation velocity of the R-wave.

For particle motion perpendicular to the direction of propagation (S-waves), C_g , the curvature can be calculated as

Seismic Design of Pipelines,

Fig. 3 Kennedy et al. (1977) model for one side of the fault

$$C_g = \frac{A_{\max}}{C_s^2} \quad (14)$$

where $A_{\max}$ is the maximum ground acceleration perpendicular to the direction of wave propagation and C_s is the propagation velocity of the S-wave.

Wave propagation with particle motion parallel to the pipeline (R-wave) would induce large axial strain in the pipeline. On the other hand, S-waves propagating parallel to the pipeline with particle motion perpendicular to the pipeline direction would induce only bending strains.

For S-waves traveling in a horizontal plane and at an angle with respect to the pipeline, the S-wave particle motion (perpendicular to its direction of propagation) would have one component parallel to the pipeline inducing axial strain, ε_g , and another component perpendicular to the pipeline inducing bending strain, ε_b , which can be calculated as

$$\varepsilon_g = \frac{V_{\max}}{2 C_s} \quad (15)$$

and

$$\varepsilon_b = \frac{\pi D V_{\max}}{\lambda C_s} \quad (16)$$

where ε_b is the upper bound bending strain (maximum), $V_{\max}$ is the peak ground velocity, C_s is the apparent propagation velocity of the S-wave, λ is the wavelength, and D is the pipe diameter.

The bending strains induced in a pipeline due to traveling waves (S-waves, L-waves, or the vertical component of R-waves) are generally

small compared to the axial strains induced in the ground by the traveling waves.

Pipelines Response to Faulting

This section presents the response of continuous pipelines subject to fault offsets. PGD due to faulting can be resolved into two components: longitudinal PGD (parallel to the pipeline) and transverse PGD (perpendicular to the pipeline) axis. In the case of “normal fault” type (see Fig. 1), the pipeline will be subjected to bending axial tensile force, caused by the transverse and longitudinal components, respectively. In this case, tensile rupture would be the most probable failure mechanism. In the “reverse fault”-type case, the pipeline will be subjected to bending axial compressive force, caused again by the transverse and longitudinal components, respectively. In this case, buckling would be the most likely failure mechanism. In the last case of “strike slip fault,” the pipeline can be subjected to either tension or compression depending on the intersection angle between the pipeline and the fault and pipe and the relative movement at the fault.

Kennedy et al. (1977) proposed a simplified method to analyze the tensile and bending behavior of pipelines due to fault movements. Figure 3 shows the Kennedy et al. model for one side of the fault.

According to Kennedy et al. (1977), the total strain in the pipe (bending + tensile) is given by

$$\varepsilon = \varepsilon_a + \varepsilon_b = \frac{\Delta L}{L} + \frac{D}{2R_c} \quad (17)$$

where ΔL is the total elongation of the pipeline, L is the total length of the pipeline, D is the pipe diameter, and R_c is the radius of curvature of the curved portion. R_c can be estimated by

$$R_c = \frac{\sigma \pi D t}{P_u} \quad (18)$$

where σ is the axial stress at fault crossing and P_u is the peak lateral pipeline-soil interaction force per unit length which can be calculated using the 1984 ASCE guideline using the following relations for sand and clay, respectively:

For sand

$$P_u = \gamma H N_{qh} D \quad (19)$$

For clay

$$P_u = c_u N_{ch} D \quad (20)$$

where γ is the unit weight of the soil, H is the embedment depth of the pipeline, and N_{qh} and N_{ch} are the horizontal bearing capacity factors for sand and clay, respectively. Figure 4 presents

horizontal bearing capacity factors for sand and clay after Hansen (1961).

The total elongation of the pipeline, ΔL , can be estimated using the following equation:

$$\Delta L = \delta_f \cos \beta + \frac{(\delta_f \sin \beta)^2}{3L_c} \quad (21)$$

where δ_f is the average fault displacement, β is the fault angle, and L_c is the horizontal projection length of the laterally deformed pipeline (see Fig. 3).

L_c can be approximately calculated using the following simplified equation:

$$L_c = \sqrt{R_c \delta_f \sin \beta} \quad (22)$$

Pipelines Response to Longitudinal PGD

This section presents the response of continuous pipelines subject to longitudinal permanent ground deformations, PGD, where the soil movement is in the same direction as the pipeline.

Seismic Design of Pipelines,

Fig. 4 Horizontal bearing capacity factors for sand and clay (Reproduced after Hansen 1961)

O'Rourke et al. (1995) proposed an inelastic pipeline model to analyze the response of pipelines to longitudinal PGD. Figure 5 shows the considered model. To develop this model O'Rourke et al. utilized an idealized block pattern in which a mass of soil having length L moves down a slight incline. The soil displacement on either side of the PGD zone is zero, while the soil displacement within the zone is a constant value δ .

In O'Rourke et al. model, a block of soil between Points B and D moves to the right pulling the pipe laterally with it with the soil forces acting on the pipeline within the PGD zone to the right. On the other hand, the soil between Points A and B and the soil between Points D and E resist the pipeline movement and these soil restraint forces are directed to the left. The combined pipeline-soil interaction forces result in a region of pipe axial tension between points A and B and a region of axial compression between points D and E. The conditions outlined in Fig. 5 correspond to the case where the PGD, δ , is comparatively large and the length of the PGD zone, L , is comparatively short. In that case, the maximum pipe displacement is less than the ground displacement and the pipe strain is controlled by L .

Figure 6 presents the other possibility of the O'Rourke et al. model where the length of the PGD zone is relatively large while the amount of PGD is comparatively short. Also in this case, there is still axial pipe tension between points A and B and axial compression between points D and E; however, the zone is long enough that the pipe displacement matches that of the ground between Points C and D where the axial force and strain in the pipe are zero.

As it can be seen from Figs. 5 and 6, the axial force in the pipeline in the segment AB is linearly proportional to the distance from Point A. Accordingly, the pipelines strain and displacement can be evaluated using the following Ramberg-Osgood model relations:

$$\varepsilon(x) = \frac{\beta_p x}{E} \left[1 + \frac{n}{1+r} \left(\frac{\beta_p x}{\sigma_y} \right)^r \right] \quad (22)$$

$$\delta(x) = \frac{\beta_p x^2}{E} \left[1 + \frac{2}{2+r} \frac{n}{1+r} \left(\frac{\beta_p x}{\sigma_y} \right)^r \right] \quad (23)$$

where n and r are Ramberg-Osgood parameters (given in Table 1 below), E is the modulus of elasticity of steel, σ_y is the effective yield stress, and β_p is the pipe burial parameter, defined as the friction force per unit length t_u divided by the pipe cross-sectional area A .

The pipe burial parameter β_p can be obtained from the following:

For sand

$$\beta_p = \frac{\tan \varphi \gamma H}{t} \quad (24)$$

For clay

$$\beta_p = \frac{\alpha c_u}{t} \quad (25)$$

where φ is the angle of shear resistance, γ is the effective unit weight of the soil, H is the embedment depth of the pipeline, α is the adhesion factor for clay, c_u is the undrained cohesion of the clay (see Fig. 7 below), and t is the pipe wall thickness.

Wrinkling of the Pipe Wall in Compression

Substituting a critical local buckling strain into Eq. 22, one can obtain the critical length of PGD zone L_{cr} . This can then be used to calculate the critical ground movement δ_{cr} from Eq. 23. The critical strain in compression may be taken as $0.175 t/R$.

Pipeline Response to Transverse PGD

This section presents the response of continuous pipelines subject to transverse permanent ground deformations, PGD, where the soil movement is perpendicular to the pipeline. When subjected to transverse PGD, the pipeline will stretch and bend as it attempts to conform to the transverse ground movement profile. In this case, the failure

Seismic Design of Pipelines, Fig. 5 O'Rourke et al. model to analyze the response of pipelines to longitudinal PGD

mechanism of the pipeline will be governed by the relative magnitude of the axial tensile strain and the bending strain. If the tensile strain is relatively small, the pipe wall may buckle in compression due to excessive bending. Instead, if tensile strain is relatively large, the pipe may rupture in tension due to the combined effects of the tensile and bending stresses.

In general, the response to transverse PGD is a function of the magnitude of PGD, the width of the PGD zone, and the pattern of ground deformation. Two types of transverse ground deformation patterns are discussed here: the spatially distributed transverse PGD pattern and the abrupt transverse PGD pattern. Figure 8 shows sketch of the considered patterns.

Seismic Design of Pipelines, Fig. 6 O'Rourke et al. model to analyze the response of pipelines to longitudinal PGD (PGD zone is relatively large, while the amount of PGD is comparatively short)

Spatially Distributed Transverse PGD

O'Rourke (1989) proposed a simple model to analyze the response of pipelines to spatially distributed transverse PGD. In this model O'Rourke considered two types of response (wide and narrow width PGD zones) as shown in Fig. 9 below. In the wide width PGD zone, the

pipeline is relatively flexible and its lateral displacement is assumed to closely conform to the soil outline. Accordingly, the pipeline strain is expected to be mainly due to the ground curvature (i.e., displacement controlled). On the other hand, for the narrow width PGD case, the pipeline is relatively stiff and the pipeline lateral

displacement is significantly smaller than that of the soil. Hence, the pipeline strain is anticipated to be due to loading at the pipeline-soil interface (i.e., load controlled).

The maximum bending strain, ε_b , in the pipeline is given by the following:

– For the wide width PGD zone

$$\varepsilon_b = \pm \frac{\pi^2 \delta D}{W^2} \quad (26)$$

– For the narrow width PGD zone

$$\varepsilon_b = \pm \frac{p_u W^2}{3\pi E t W^2} \quad (27)$$

And the average axial tensile strain, ε_a , in the pipeline is estimated by the following:

Seismic Design of Pipelines, Table 1 Yield stress and Ramberg-Osgood parameters for mild steel and X-grade steel

	Grade B	X-42	X-52	X-60	X-70	X-80
Yield stress (MPa)	241	290	359	414	483	552
n	10	15	9	10	5.5	16
r	100	32	10	12	16.6	16

Seismic Design of Pipelines,

Fig. 7 Adhesion factors
(Reproduced after Honegger and Nyman 2004)

– For the wide width PGD zone

$$\varepsilon_a = \left(\frac{\pi}{2}\right)^2 \left(\frac{\delta}{W}\right)^2 \quad (28)$$

– For the narrow width PGD zone

The axial tension in this case is small and neglected.

where δ is the magnitude of the PGD, D is the pipe diameter, W is the length of the PGD zone, P_u is the maximum lateral force per unit length at the pipeline-soil interface, E is the elastic modulus of the pipeline material, and t is the pipe wall's thickness.

Abrupt Transverse PGD

Parker et al. (2008) proposed a simple model to analyze the response of pipelines to transverse PGD. Figure 10 presents the geometric and force details of the model. In this model the width of the abrupt transverse PGD is $2W_1$. Within this width the pipeline is subject to a lateral force per unit length P_{u1} . This lateral load is resisted by soil resistance forces P_{u2} over a distance W_2 on each side of the abrupt transverse PGD zone (see Fig. 10). Therefore, from horizontal equilibrium in the direction of pipeline, we get

$$P_{u1}W_1 = P_{u2}W_2 \quad (29)$$

The tensile force in the pipeline is assumed to be a constant value T_o within the PGD zone. Beyond the margins the pipeline axial tension decreases linearly at Points C and E to zero at Points A and G (see Fig. 10).

According to Parker et al. (2008), the total elongation due to the pipeline deformation

(Point B to Point F) can be estimated using the following equation:

$$\Delta L = \frac{1}{3} P_{u1}^2 W_1^3 (1 + P_{u1}/P_{u2}) / T_o^2 \quad (30)$$

Thus, the axial pipe strain is calculated as

$$\varepsilon_a = \frac{\Delta L}{L} \quad (31)$$

and the bending strain in the pipeline can be evaluated as

$$\varepsilon_b = \frac{D P_{u1}}{2 T_o} \quad (32)$$

Pipelines in Liquefied Soil

It is common practice that pipelines are buried at depths of 2 m or less from the ground surface. Thus, the top of the susceptible liquefiable soil layer is commonly located below the bottom of the pipeline. However, in some cases when the pipeline is buried at a river bed in saturated sand, for example, the soil surrounding the pipeline may liquefy during strong seismic shaking event. In this case,

Seismic Design of Pipelines, Fig. 8 Sketch of the considered patterns

Seismic Design of Pipelines,
Fig. 9 O'Rourke (1989)
model to analyze the
response of pipelines to
spatially distributed
transverse PGD

Seismic Design of Pipelines, Fig. 10 Geometric and force details of the Parker et al. (2008) model

the pipeline will probably deform laterally following the flow of the liquefied soil downward a mild slope or move upward due to buoyancy, particularly when something restrains the pipeline at one point or a compressive load acts on the pipeline.

Horizontal Movement

When a pipeline is surrounded by liquefied soil, the pipeline may move laterally due to the flow of liquefied soil downslope. The response of a buried pipe surrounded by liquefied soil subject to spatially distributed transverse PGD can be analyzed using the O'Rourke (1989) method presented earlier.

Vertical Movement

When a pipeline is surrounded by liquefied soil, the pipeline may uplift due to the buoyancy and moves upward. Hou et al. (1990) proposed analytical method to analyze the response of pipelines subjected to vertical movements. According to Hou et al. (1990), the uplifting force per unit length, P_{uplift} , acting on the pipeline within the liquefied zone is given by

$$P_{\text{uplift}} = \frac{\pi D^2}{4} (\gamma_{\text{soil}} - \gamma_{\text{contents}}) - \pi D t \gamma_{\text{pipe}} \quad (33)$$

where D is the pipe diameter, γ_{soil} is the unit weight of the liquefied soil, γ_{contents} is the unit weight of the contents inside the pipe (water, oil, gas, etc.), γ_{pipe} is the unit weight of the pipe material, and t is the pipe wall's thickness.

The maximum uplift displacement and/or the spacing for pipeline restraints is given by (see Fig. 11 below)

$$A \delta_{\text{max}}^3 + 16 I \delta_{\text{max}} - \frac{16 P_{\text{uplift}} W_s^4}{E \pi^5} \quad (34)$$

and the maximum strain in the pipeline is then given by

$$\epsilon_{\text{max}} = \pm \frac{\pi^2 \delta_{\text{max}} D}{W_s^2} + \frac{\pi^2 \delta_{\text{max}}^2}{4 W_s^2} \quad (35)$$

where A is the cross-section area, I is the moment of inertia, W_s is the spacing of the restraints, and E is the elastic modulus of the pipe's material.

Seismic Design of Pipelines, Fig. 11 Profile of pipeline crossing liquefied zone

Seismic Design of Pipelines,

Fig. 12 External forces on the buried pipeline by the adjacent soil during seismic shaking

Seismic Design Guidelines and Pipeline-Soil Interaction

The pipeline-soil interaction effect exerts external forces on the buried pipeline by the adjacent soil when seismic motions are provided. The type of soil around the pipeline plays a significant role in its seismic behavior. In general, the soil displacement will produce friction like forces at the pipeline-soil interface (see Fig. 12 below). The overall seismic performance of buried pipeline is strongly related to the force-deformation relationship at the pipeline-soil interface (the p-y curves). For cohesionless soils, the probability of liquefaction becomes higher in loose materials. In cohesive soils, softer soils will undergo greater differential settlement due to consolidation and higher amplification effects and accordingly greater interaction forces.

Pipelines in Competent Non-liquefied Soil

The 1984 ASCE Guidelines suggest for the purpose of analysis idealized elastoplastic models for the force-deformation relationship at the pipeline-soil interface (see Fig. 13 below).

Longitudinal Movement

In this case the relative movement is parallel to the pipeline which results in axial forces at the pipeline-soil interface. The 1984 ASCE Guidelines provide relations for both cohesionless and cohesive soils. For cohesionless materials, the longitudinal resistance is due to the friction in the longitudinal direction at the pipeline-soil interface. The normal pressure which leads to the axial friction is the overburden and the lateral soil pressures. In the 1984 ASCE Guidelines, the normal pressure is taken as the average of the vertical and at rest lateral soil pressures acting

Seismic Design of Pipelines, Fig. 13 Idealized elastoplastic models for the force-deformation relationship at the pipeline-soil interface (Reproduced after ASCE 1984)

on the pipeline. (The 1984 ASCE Guidelines assumes $X_u \cong 2.5 \sim 5.0$ mm).

$$t_u = \pi D \gamma H \left(\frac{1 + k_o}{2} \right) \tan k\varphi \quad (36)$$

For cohesive materials, the longitudinal resistance is proportional to the adhesion at the pipeline-soil interface:

$$t_u = \pi D \alpha c_u \quad (37)$$

where D is the pipe diameter, γ is the effective unit weight of the soil, H is the depth of the pipeline, φ is the angle of shear resistance, k_o is the coefficient of lateral soil pressure at rest, k is a friction factor, α is the adhesion factor (given in Fig. 7), and c_u is the undrained shear strength of the soil.

Transverse-Horizontal Movement

In this case the relative movement is perpendicular to the pipeline which results in transverse-horizontal forces at the pipeline-soil interface. The 1984 ASCE Guidelines provide relations for both cohesionless and cohesive soils. For cohesionless materials, the maximum soil resistance in horizontal transverse direction may be calculated using the following equation:

$$P_u = \gamma H D N_{qh} \quad (38)$$

and the maximum elastic relative displacement in horizontal transverse direction is

$$y_u = \begin{cases} (0.07 \sim 0.10)(H + D/2) & \text{for loose sand} \\ (0.03 \sim 0.05)(H + D/2) & \text{for medium sand} \\ (0.02 \sim 0.03)(H + D/2) & \text{for dense sand} \end{cases} \quad (39)$$

For cohesive materials, the maximum soil resistance in horizontal transverse direction may be evaluated using the following equation:

$$P_u = c_u N_{ch} D \quad (40)$$

The maximum elastic relative displacement in horizontal transverse direction is

$$y_u = (0.03 \sim 0.05)(H + D/2) \quad (41)$$

where γ is the unit weight of the soil, H is the embedment depth of the pipeline, and N_{qh} and N_{ch} are the horizontal bearing capacity factors for sand and clay, respectively (Fig. 4).

Pipelines in Liquefied Soil

The response of continuous pipelines buried in liquefied soil layer is very sensitive to the

stiffness of the soil (Suzuki et al. 1988; Miyajima and Kitaura 1989). Based on several experimental results, it is recommended that the stiffness of liquefied soil ranges from 1/100 to 3/100 of that for non-liquefied soil (Yoshida and Uematsu 1978; Matsumoto et al. 1987; Yasuda et al. 1987; Tanabe 1988). Accordingly, the reduced stiffness will be used at the pipeline-soil interface. Analysis is then performed using the same procedures as in the competent non-liquefied soil case (on the conservative side).

Summary

This chapter focused on the seismic analysis and design of pipelines. In seismic events, buried pipelines can be damaged mainly by either the permanent ground deformations (PGD) or by the transient seismic wave propagation. Hence, different analysis methods for pipelines subjected to permanent ground deformation (PGD) or transient seismic wave propagation hazards were presented and discussed in details. In addition, the response of continuous pipelines subject to fault offsets was discussed. Also, several methods were introduced to predict the response of pipelines to either longitudinal or transverse PGD.

Earthquake shaking may trigger the liquefaction of saturated loose cohesionless soils. The liquefaction process increases the pore water pressure in the ground to a level where the effective stress approaches zero at which point the soil loses entirely its shear strength. A separate section in this chapter presented and discussed methods of analyzing and designing pipelines buried in liquefiable soils.

The overall seismic performance of buried pipelines is strongly related to the pipeline-soil interaction. Consequently, this chapter dedicated a section to provide guidelines for the seismic design of pipelines considering the pipeline-soil interaction effects as it plays a significant role in its seismic behavior.

Introduction

The complete enclosure in soil or rock makes their seismic behavior different than that of aboveground structures or superstructures. Underground structure seismic response is constrained by seismic response of the surrounding soil and cannot experience free vibrations as is the case for aboveground structures. This section focuses on the seismic analysis and design of large linear underground structures commonly used for metro structures, highway tunnels, and large water/sewage transportation ducts in urban areas and can be grouped into three broad

Seismic Design of Tunnels, Fig. 1 Typical cross sections of underground structures

categories: (1) bored or mined tunnels, (2) cut-and-cover tunnels, and (3) immersed tunnels (Fig. 1).

The section starts with a selected review of performance of underground structures during seismic events. This is followed by presentation of a performance-based framework for design and analysis of underground structures considering both permanent and transient deformations. A number of seismic design issues are then discussed including vertical ground shaking and response, interaction of temporary and permanent structures, impact of superstructure and adjacent structures, transitions and tunnel joints, seismic retrofit of existing facilities, design considerations for structural support members, and precast tunnel lining.

Performance of Underground Facilities During Seismic Events

Based on several studies that documented earthquake damage to underground facilities in the past and the behavior of underground facilities

in recent large magnitude earthquakes (e.g., Tohoku, Japan, 2011; Maule, Chile, 2010), underground structures suffer appreciably less damage than surface structures. However, damage or failure of a limited section of an underground structure can be disruptive to post-earthquake recovery or operation in densely populated urban areas as such damage can interrupt the function of an entire system whether it is part of a mass transit or vehicular transportation network or large water or sewage transportation tunnels.

Damage is related to a number of parameters including ground motion intensity, ground conditions, and structural support system. Shallow tunnels tend to be more vulnerable to earthquake shaking than deep tunnels, and those constructed in soil can undergo more deformation than those constructed in competent rock. Circular bored tunnels are less susceptible to earthquake damage than cut-and-cover tunnels. Shaking damage can be reduced by stabilizing the ground around the tunnel and by improving the contact between the lining and the surrounding soil using grouting. Stiffening the lining without stabilizing the

Seismic Design of Tunnels, Fig. 2 Street view of Dakai subway station collapse (Iida et al. 1996)

surrounding poor ground may only result in excessive seismic forces in the lining. Damage at tunnel portals may be caused by slope instability (Hashash et al. 2001).

Underground Structures in the United States

The Bay Area Rapid Transit system (BART) in San Francisco, California, sustained the 1989 Loma Prieta earthquake without damage and was operational after the earthquake. It consists of underground stations and tunnels embedded in soft bay mud deposits connected to Oakland via the transbay-immersed-tube tunnel. It was one of the first underground facilities designed with seismic considerations: special seismic joints were designed to accommodate differential movements. Limited displacements were measured at that joint.

During the same earthquake, the Alameda Tubes, a pair of immersed-tube tunnels that connect Alameda Island to Oakland in California, experienced structural cracking on the ventilation buildings and limited water leakage due to liquefaction of loose deposits above the tubes.

The 1994 Northridge earthquake caused no damage to concrete lining of bored tunnels of the metro system in Los Angeles, California (Hashash et al. 2001).

Underground Structures in Japan

The Dakai subway collapse (Fig. 2) during the 1995 Hyogoken-Nambu earthquake in Kobe, Japan, was the first collapse of an urban underground structure due to earthquakes shaking. The collapse experienced by the center concrete columns (Fig. 3) was due to lack of shear reinforcement, leading to a collapse of the ceiling slab and settlement of the soil cover. The 1962 station design did not include specific seismic provisions. However, in the 2011 Tohoku earthquake, the underground subways in Sendai experienced strong shaking with no reports of damage. Only a water distribution plant in Kashima City and a wastewater treatment plant in Itako City were observed to have been damaged by liquefaction. The damages include uplift of buried tanks, offsets in underground tunnels, damage to support utilities, and damage to major trunk lines on and off the site (Ashford et al. 2011).

Underground Structures in Taiwan

The 1999 Chi-Chi earthquake did not cause visible signs of damage in several highway tunnels located in central Taiwan. The main damage occurred at tunnel portals because of slope instability. No damage was reported in the Taipei subway, located 100 km from the ruptured fault

Seismic Design of Tunnels, Fig. 3 Dakai subway station collapse (Iida et al. 1996)

zone (Fig. 4). However, some tunnels in mountainous areas were severely damaged due to slope failure (Fig. 5).

Underground Structures in Turkey

The August 17, 1999, Kocaeli earthquake had minimal impact on the Bolu twin tunnels, a 1.5-billion-dollar project under construction at that time. It had an excavated section of 15 m tall by 16 m wide and crossed several minor faults parallel to the North Anatolian Fault. After the earthquake, continuous monitoring showed no movement due to the earthquake. The November 12, 1999, earthquake caused collapse of both tunnels 300 m from its eastern portal, in a clay gauge material in the unfinished section (Hashash et al. 2001).

Underground Structures in Chile

Cut-and-cover highway box structures with three lanes of traffic in one direction and approximately 1 km long constructed in relatively stiff

gravels, the Santiago Metro tunnels and underground stations, and highway tunnels on the southbound of Route 5 appeared to be undamaged by the 2010 Maule earthquake in Chile, as shown in Fig. 6. In the northbound of Route 5, “La Calavera” tunnel near Calera has a rock block dislodged, but the tunnel was old and had problems before the earthquake (Elnashai et al. 2010).

In summary, well-engineered underground structures performed well even under strong shaking in recent earthquakes in different parts of the world. However, underground structures are vulnerable to permanent ground displacements such as liquefaction, slope stability, and fault displacement. There is also vulnerability to transient ground motions when insufficient structural detailing is provided, the underground structure is constructed in loose ground, masonry lining is used, or near field effects are present.

Performance-Based Seismic Evaluation Framework

Underground structures under earthquake effects can undergo permanent deformations and/or transient deformations. Factors influencing these effects include shape, dimensions, and depth of the structure, properties of the surrounding soil or rock, properties of the structure, and severity of ground shaking (Hashash et al. 2001). Table 1 summarizes a performance-based framework for seismic design and analysis of underground structures. The framework consists of three main steps: definition of seismic environment, evaluation of ground response to shaking, and assessment of structure response due to seismic shaking.

Step 1: Definition of Seismic Environment

Seismic analysis of underground structures starts with site-specific definition of its seismic environment. A detailed field and laboratory investigation program is necessary; the field investigation program should include definition of the site stratigraphy and direct measurements of shear wave velocity profiles and cone

Seismic Design of Tunnels, Fig. 4 Slope failure at tunnel portal, Chi-Chi earthquake, central Taiwan (Hashash et al. 2001)

penetration resistance of soft soils as well as assessment of potential geo-hazards including slope instability, fault displacement, and lateral spreading. Appropriate static and cyclic laboratory tests for major soil units are also required.

Site-specific probabilistic and/or deterministic seismic hazard analyses, as well as hazard analyses using conditional (mean) spectra, are needed to define seismic hazard levels for permanent condition of the structure (operational and maximum levels). Increasingly seismic hazard, using a shorter return period, is being considered for temporary conditions during construction.

Seismic performance criteria selection is a crucial aspect in the design of an underground structure. Performance objectives include explicit target performance of the structure and system performance. Performance objectives are not purely technical requirements and should include owner and user requirements, policy considerations, and life-cycle costs. It is an iterative process

based on analysis findings to answer the question of what is feasible and at what cost as illustrated in Fig. 7.

Often a two-level criterion is adopted: operating design earthquake (ODE) and maximum design earthquake (MDE). Those are defined using response spectra developed in the seismic hazard analysis. A suite of three component motions is needed for each of the design earthquake levels for site response analysis and soil-structure interaction modeling. It is preferred to use recorded motions instead of synthetic motions to spectrally match the target spectra. Ground motion spatial incoherence must be taken into account for long structures including (1) wave passage, (2) extended source effects, (3) ray-path effects, and (4) local site effects. One-dimensional equivalent linear and nonlinear site response analyses are conducted to assess how the ground motion is affected by the soil column. One-dimensional site response

Seismic Design of Tunnels, Fig. 5 Chi-Shue tunnel before and after Chi-Chi earthquake (Wang et al. 2001)

Seismic Design of Tunnels, Fig. 6 Left: Highway box structures in Santiago, Right: Highway tunnel in Route 5 South

Seismic Design of Tunnels, Table 1 Performance-based framework for design and analysis of underground structures

analyses are used in the analysis of underground structures to:

- (a) Obtain free-field racking deformations (differential sideways movements between the top and bottom elevations of rectangular structures) along the underground structure height which can be used in pseudo-static soil-structure interaction.
- (b) Obtain input motions for dynamic soil for dynamic soil-structure interaction analysis.
- (c) Obtain strain-compatible soil properties for use in pseudo-static and dynamic soil-structure interaction.
- (d) Assess potential liquefaction and ground failure.

Step 2: Evaluation of Ground Response to Shaking

Evaluation of ground response to shaking can be divided into permanent deformations or ground failure and transient deformations or ground shaking.

Permanent deformations or ground failure includes liquefaction, slope instability, and fault displacement. Liquefaction, prevalent in loose sand and fill deposits, can result in generation of sand boils, loss of shear strength, lateral spreading, and slope failure. Tunnels in liquefiable deposits can experience increased lateral pressures, loss of lateral passive resistance, flotation or sinking, lateral displacements if lateral spreading happens, permanent settlement, and compression/tension failure after soil consolidation. A landslide intercepting a tunnel can result in concentrated shearing displacements and collapse of a cross section. The potential for these failures is greatest when a pre-existing landslide intersects the tunnel, in shallower parts of tunnel, and at tunnel portals. An underground structure may have to pass across an active fault zone; in these situations the tunnel must tolerate the expected displacements. The design for permanent deformations is discussed in section “[Design for Permanent Deformations.](#)”

Transient deformations can be quite complex due to interaction of seismic waves with surficial

Seismic Design of Tunnels, Fig. 7 Performance-based design procedure after Hamburger and Hooper (2011)

deposits. Underground structures undergo three primary modes of deformation during seismic shaking: compression-extension, longitudinal bending, and ovaling/racking. The design for transient deformations is discussed in section “[Performance Evaluation Under Transient Ground Deformations](#).”

Step 3: Assessment of Structure Behavior Due to Seismic Shaking

The evaluation of structure behavior will be primarily a deformation controlled soil-structure interaction problem. Pseudo-static and dynamic soil-structure interaction approaches have been used in the evaluation of structure response and are discussed in section “[Performance Evaluation Under Transient Ground Deformations](#).”

Section “[Additional Seismic Performance Issues](#)” discusses additional seismic design issues such as vertical ground shaking and response;

interaction of temporary and permanent structures; permanent changes in state of stress of soil; impact of superstructure and adjacent structures; tunnel joints such as portals, stations, and tunnel segment; seismic retrofit of existing facilities; design considerations for structural support members; precast tunnel lining; and seismic design of buried reservoirs.

Design for Permanent Deformations

Designing underground structures for permanent deformations may not be viable, but ground stabilization techniques can help prevent large deformations. Some solutions include ground improvement, drainage, soil reinforcement, grouting, earth retaining systems, or even removing problematic soils or relocating the tunnel alignment.

Underground Structures Crossing Active Faults

In the Century Area Tunneling Safety and Fault Investigations TAP report for the Los Angeles Metro (Cording et al. 2011), some recommendations are provided for consideration when an underground tunnel segment crosses an active fault:

- The segments must be designed to accommodate fault displacement without collapse and with the capability of being repaired.
- The alignments should be selected so that the tunnel crosses at a relatively sharp angle to the fault zone to minimize the length of tunnel that must accommodate fault displacements.
- Methods employed to allow fault displacement on a tunnel lining include excavating to a larger section at the crossing to facilitate realignment, providing the tunnel with a strong but flexible lining like ductile steel segments or articulated joints, and placing crushable backpacking material around the structural lining.
- As there is no precedent of placing metro underground stations on active faults, designing for it will be extremely difficult and cost-prohibitive. If possible, it is advisable to avoid this scenario.

The design approach for tunnels crossing active faults will change depending on the displacement magnitude and the tunnel width over which the displacement is distributed:

- (a) If fault displacements are small and/or distributed over a relatively wide zone, providing articulation of the tunnel lining through ductile joints is a possible solution. The closer the joint spacing, the better the tunnel performance will be; this is more viable in soft soils where displacements can be effectively redistributed over the tunnel lining. The tunnel can then deform in an S-shape through the fault zone without rupture. It is always necessary to keep the tunnel watertight when using joints.
- (b) If large displacements are concentrated in a narrow zone, retrofit will consist of enlarging the tunnel section across and beyond the displacement zone. The length over which the enlargement is made is a function of fault displacement and permissible curvature of the road or track; the longer the enlarged tunnel, the smaller the post-earthquake curvature (Power et al. 1996). This solution has been implemented in the San Francisco BART system and Los Angeles Metro rapid transit tunnel system. Concrete-encased steel ribs provide sufficient ductility to accommodate distortions with little strength degradation. Under axial displacements, even though compression is more damaging to the tunnel lining than extension, both will result in unacceptable water inflow. A solution for water tightness is flexible couplings (Wang 1993), used for the Southwest Ocean Outfall in San Francisco. Cellular concrete may also be used within the enlarged tunnel, because it has a low yield strength that can minimize the loads on the tunnel liner while also providing adequate resistance for normal soil pressures and other seismic loads.

Estimating fault displacement is a key issue to design tunnels crossing active faults. One option to estimate fault displacement is using empirical relationships that express expected displacements in terms of some source parameter. Deterministic and probabilistic fault displacement hazard analyses can be used to assess fault displacement hazard where a displacement attenuation function is used in a probabilistic seismic hazard analysis (Coppersmith and Youngs 2000; Youngs et al. 2003).

Flotation in Liquefiable Deposits

Liquefaction evaluation is discussed elsewhere. If liquefaction is limited to soil layers above the underground structure, then it is unlikely to influence the racking deformations of the structure. However, if the structure is partially or entirely embedded in liquefiable soil, additional evaluations are required. Underground structures may experience flotation in liquefiable deposits.

Seismic Design of Tunnels, Fig. 8 Isolation principle, use of cutoff walls to prevent tunnel uplift (Schmidt and Hashash 1999)

As shown in Fig. 8a, when the tunnel experiences uplift due to flotation, the liquefied soil moves underneath the displaced tunnel and lifts it further up (Schmidt and Hashash 1999). Uplift can be prevented through isolation using cutoff walls, such as sheet pile walls; stone columns (Fig. 8b); or jet grout columns (Fig. 8c). Sheet piles with drainage capability can also reduce excess pore water pressure. The rise in excess pore water pressure is prevented at the bottom of the tunnel and in the soil underneath with these barrier walls. With longer barrier walls and a wider structure, uplift is more difficult. After the liquefaction potential is mitigated, flexible joints can be used to allow for differential displacements at tunnel connection joints.

Slope Instability and Lateral Spreading

Stabilizing the soil or changing the alignment is often the most practical way to mitigate slope instability and lateral spreading. It is challenging to design an underground structure to resist or take these movements unless the hazard is localized and the movement is small (Power et al. 1996).

Performance Evaluation Under Transient Ground Deformations

If permanent deformations are not expected, then the underground structure must be designed for transient ground deformations. In this case, the underground structure response is controlled by the ground deformation and the peak ground velocity.

The focus of underground structure seismic design is on free-field deformations of the ground and their interaction with the structure, since the inertia of the surrounding soil is large relative to the inertia of the structure. Figure 9 shows response of underground structures to seismic motions: axial compression and extension, longitudinal bending, and ovaling/racking. Axial deformations are due to seismic waves producing motions parallel to the tunnel axis, bending is due to seismic waves producing particle motion perpendicular to the longitudinal axis, and ovaling/racking is due to shear waves propagating normally to the tunnel axis. Design considerations for axial and bending deformations are generally in the direction along

Seismic Design of Tunnels, Fig. 9 Deformation modes of tunnels due to seismic waves

the tunnel axis and in the transverse direction for ovaling/racking.

There are four main approaches to tackle the design for transient deformations: free-field deformation methods, pseudo-static soil-structure interaction analyses, dynamic soil-structure interaction finite-element analyses, and dynamic earth pressure methods. The merits and drawbacks of these methods are summarized in Table 2.

Free-field deformation methods assume that the underground structure deformations are identical to those of the surrounding ground. They do not take into account soil-underground structure interaction and are most appropriate when the structure (racking) stiffness is equivalent to that of the surrounding ground.

Pseudo-static soil-structure interaction models account for the kinematic interaction between the soil and the underground structure neglecting inertial interaction. They are often used for practical design purposes when the structure is not too complex (NCHRP 611, Anderson et al. (2008)).

Nowadays, the ease of access to high performance computers makes it possible to perform

dynamic soil-structure interaction analyses within a reasonable amount of time. These types of analyses allow problems with complicated tunnel geometry and ground conditions to be solved efficiently. However, the selection of parameters for a complex problem requires expertise; therefore, it is important to always verify the computer model solution with simpler pseudo-static or closed-form solutions.

The presence of a rectangular frame structure in the ground will induce dynamic earth pressures acting upon the structure. Complex shear and normal stress distributions along the exterior surfaces of the structures are expected, but quantifying those distributions require rigorous dynamic soil-structure interaction, since they heavily depend on how the interface is modeled.

In the past, the Mononobe-Okabe method was used to calculate the seismic-induced dynamic earth pressures on underground structures. The method assumes the earthquake load is caused by inertial forces of the surrounding soil and calculates the load using soil properties and a determined seismic coefficient. This method is not applicable in the case of underground structures,

Seismic Design of Tunnels, Table 2 Comparison of seismic design approaches

Approaches	Advantages	Disadvantages	Applicability
Free-field deformation methods	1. Comparatively easy to formulate, many 1D wave propagation programs available	1. Nonconservative for tunnel structure more flexible than ground 2. Conservative for tunnel structure stiffer than ground 3. Overly conservative for tunnel structures significantly stiffer than ground 4. Less precision with highly variable ground conditions	For tunnel structures with equal stiffness to ground
Pseudo-static soil-structure interaction methods	1. Good approximation of soil-structure interaction 2. Comparatively easy to formulate 3. Reasonable accuracy in determining structure response 4. Computationally efficient 5. Sensitivity analysis can be easily performed	1. Ignores inertial effects 2. Less precision with highly variable ground 3. Shear displacement not transmitted uniformly to shallow box structures	Most conditions except for variable soil profile, shallow structures
Dynamic soil-structure interaction finite-element analysis	1. Best representation of soil-structure system 2. Best accuracy in determining structure response 3. Capable of solving problems with complicated tunnel geometry and ground conditions (significant variations in soil stiffness)	1. Computationally demanding 2. Uncertainty of design seismic input parameters may be several times the uncertainty of the analysis	All conditions
Dynamic earth pressure methods	1. Serve as additional safety measures against seismic loading	1. Lack of rigorous theoretical basis 2. Resulting in excessive deformations for tunnels with significant burial 3. Use limited to certain types of ground properties	None

since they will move with the ground and will not form an active wedge.

When designing underground structures for transient deformations, sufficient ductility is needed to absorb imposed deformations without losing the capacity to carry static loads. Care should be exercised in not increasing the stiffness of the structure as this tends to attract additional loads thus increasing the demand on the structure.

Free-Field Deformation Approach

Free-field deformations are the deformations caused by seismic waves on a given soil profile in the absence of structures or excavations. The interaction between the soil and the underground structure is neglected, but provides a first-order

estimate of the underground structure deformation. Imposing the free-field deformations directly on the underground structure can underestimate or overestimate the structure deformations.

Closed-Form Elastic Solutions

Initial estimates of strains and deformations in a tunnel can be developed using simplified closed-form solutions. There are many assumptions within the formulation of these methods:

- (a) The seismic wave field is considered as a plane of wave with the same amplitude at all locations along the tunnel, differing only in their arrival time. Wave scattering and 3D wave propagation are neglected. The results

Seismic Design of Tunnels, Fig. 10 Seismic waves causing longitudinal axial and bending strains (Power et al. 1996)

of these analyses should be interpreted with care (Power et al. 1996).

- (b) Harmonic wave propagating at a given angle of incidence in a homogeneous, isotropic, elastic medium. The critical incidence angle resulting in the maximum strain is typically used (Newmark 1967). However, the strain order of magnitude estimated by this method is useful as initial design tool and design verification method.
- (c) St John and Zahrah (1987) developed free-field solutions for axial and curvature strains due to compression, shear, and Rayleigh waves. Figure 10 shows the seismic waves causing the strains. Treating the tunnel as an elastic beam allows the calculation of combined axial and curvature deformations.

The strain bending component is relatively small compared to axial strains, but if the tunnel radius increases, the curvature contribution increases. Tunnel cracks may open and then close in the lining due to the cyclic nature of the axial strains. As long as the cracks are small, are uniformly distributed, and do not affect the performance of the tunnel, even unreinforced concrete linings are considered adequate. It is important to emphasize that the p- and s-wave velocities used are those of the deep rock. The range for s-wave is between 2 and 4 km/s and p-wave between 4 and 8 km/s (Power et al. 1996).

Ovaling and Racking Deformation

Ovaling deformations, developed by waves acting perpendicular to the circular tunnel lining, are

caused predominately by vertically propagating shear waves (Wang 1993). Ground shear distortions can be defined assuming a non-perforated ground or a perforated ground. As shown in Fig. 11, both cases ignore the tunnel lining (soil-structure interaction), where the maximum diametric strain is in terms of the maximum free-field shear strain ($\gamma_{\max}$) and the Poisson ratio (ν_m). The first can be used to approximate the behavior of a tunnel lining whose stiffness is equal to the medium it replaces. The second can be used to approximate the behavior of a tunnel lining whose stiffness can be neglected in comparison with the stiffness of the medium.

A rectangular box structure will undergo transverse racking deformations (Fig. 12) when subjected to earthquake shear distortions. Racking deformations are defined as the differential sideways movements between the top and bottom elevations of rectangular structures. If an initial calculation is needed, it can be calculated based on St John and Zahrah (1987) equations.

Numerical Analysis

Many computer programs are available to estimate free-field shear distortions: SHAKE (Schnabel et al. 1972), FLUSH (Lysmer et al. 1975), D-MOD (Matasovic 1993), and DEEPSOIL (Hashash et al. 2011; Hashash and Park 2001), among others. One-dimensional site response analyses can be used to characterize the change in the propagating ground motions on variable soil profiles, but these analyses only take into consideration vertically propagating shear waves. However, these are the waves that

Seismic Design of Tunnels, Fig. 11 Free-field shear distortions of perforated and non-perforated ground

Seismic Design of Tunnels, Fig. 12 Typical free-field racking deformation imposed on a rectangular frame (Wang 1993)

carry most of the seismic energy. The analyses can be performed in equivalent linear frequency domain or nonlinear time domain. The resulting free-field shear distortion can be expressed in the form of shear strain or shear deformation profile with depth.

Applicability of Free-Field Deformation Approach
The free-field deformation approach is a simple and effective design tool when earthquake-induced ground motions are small. However, in structures located within soft soil profiles, the method gives overly conservative designs, because free-field ground distortions in these soils are large. It also neglects the difference in stiffness between the lining and the surrounding soil. The presence of an underground structure modifies the free-field deformations; methods to model this interaction will be described in the following sections.

Pseudo-static Soil-Structure Interaction

In pseudo-static soil-structure interaction analyses, the soil and structure inertia due to seismic shaking is neglected. The problem is simplified to that of a structure in a soil medium subjected to simple shear on horizontal and vertical planes.

The beam-on-elastic foundation approach is used to model soil-structure interaction effects. Both the lining and the medium are assumed to be linear elastic. Wang (1993) presents a summary of closed-form elastic solutions for axial force and moment developed for circular tunnels due to seismic waves propagating along and perpendicular to the tunnel axis. Adding stiffness and strength to the structure may attract more forces, so a better solution would be to add ductility. These solutions are dependent on the estimates of appropriate spring coefficients compatible with anticipated displacements and wave lengths. They are often limited to idealized seismic wave forms.

Most pseudo-static SSI analyses focus on the interaction of vertically propagating shear waves with the transverse section of a tunnel. These analysis approaches are described next.

Transverse: Ovaling Deformations of Circular Tunnels

Peck et al. (1972) proposed closed-form solutions in terms of thrust, bending moments, and displacement under external loading. The lining response was a function of structure compressibility and flexibility ratios, in situ overburden pressure, and at-rest earth coefficient. To adapt to seismic loading, the free-field shear stress replaces the in situ overburden pressure and earth coefficient. The stiffness of the tunnel relative to the ground is measured by the compressibility (C) and flexibility (F) ratios. Those are the extensional stiffness and flexural stiffness of the medium relative to the lining.

Under this framework, Wang (1993) presented solutions for the diametric strain, the maximum thrust, and the bending moment under full-slip conditions, meaning normal force but no tangential shear force are present between the lining and the medium. For most cases the interface condition is between full slip and no slip. Slip interface can only happen in tunnels in soft soils or cases of severe seismic loading and full-slip assumption may lead to underestimation of the maximum thrust. As shown in Wang (1993) and NCHRP 611 (Anderson et al. 2008), for ground Poisson's ratio less than 0.5, thrusts decrease with decreasing compressibility ratio, but for Poisson's ratio of 0.5, the thrust response is independent of compressibility. The normalized lining distortion can be a plotted as function of flexibility ratio, as shown in Fig. 13. When $F < 1.0$, the lining is considered stiffer than the ground and deforms less than the ground. When $F > 1.0$, the lining is expected to deform more than the free field with an upper limit equal to the perforated ground case as described in Table 3. Penzien (2000) provides an analytical procedure to evaluate racking deformations of rectangular and circular tunnels. His solutions for ovaling deformations in terms of thrust and moment are very close to those of Wang (1993) for full-slip condition. However, the value of thrust for no-slip condition is much smaller in Penzien (2000) than in Wang (1993), differing in one order of magnitude.

Seismic Design of Tunnels, Fig. 13 Normalized lining deflection vs. flexibility ratio, full-slip interface, circular lining (Wang 1993)

Seismic Design of Tunnels, Table 3 Explanation of flexibility ratio

Flexibility ratio F	Meaning
$F \rightarrow 0$	The structure is rigid, so it will not rack regardless of the distortion of the ground
$F < 1$	The structure is stiff relative to the medium and will therefore deform less. Usually soft soil, and racking deformations are large
$F = 1$	The structure and medium have equal stiffness, so the structure will undergo approximately free-field distortions
$F > 1$	The structure racking stiffness is smaller than that of the soil. Usually stiff soil, and racking deformations are small
$F \rightarrow \infty$	The structure has no stiffness, so it will undergo deformations identical to the perforated ground

Hashash et al. (2005) compared the two analytical solutions to finite-element method numerical analyses to validate which of the solutions provide the correct solution to this problem.

The results from the numerical analyses agree with Wang (1993) solutions, highlighting the limitations of the other analytical solution. Sedarat et al. (2009) show that interface condition between the tunnel lining and the surrounding soil has an important impact on the computed thrust in the lining but limited impact on computed lining deformation.

Transverse: Racking Deformations of Rectangular Tunnels

Box-shaped cut-and-cover tunnels, common for transportation tunnels, have seismic characteristics different from circular tunnels because the walls and slabs of the box-shaped tunnels are stiffer. They are also often placed at shallower depths compared to circular tunnels. Therefore, it is important to carefully consider the soil-structure interaction due to increased stiffness and the increased seismic ground deformations at shallow depths (Hashash et al. 2001). Numerical analyses are often employed to compute the response of the tunnel structure to deformation of the surrounding soil.

Seismic Design of Tunnels, Fig. 14 Racking ratio, free-field and structure racking (Hashash et al. 2010)

Wang (1993) and Anderson et al. (2008) employed such techniques to develop relationships between racking ratio and flexibility (Fig. 14).

Huo et al. (2006) present an analytical solution for deep rectangular structures with a far-field shear stress. Complex variable theory and conformal mapping were used to develop the solution of structures in homogeneous, isotropic, elastic medium.

The relative stiffness between soil and structure, structure geometry, input earthquake motions, and tunnel embedment depth are factors that contribute to the soil-structure interaction effect. The most important of those is the flexibility ratio (F) that refers to the shear stiffness of the soil relative to the structure that replaces it (Wang 1993):

$$F = \frac{G_m \cdot B}{P \cdot H}$$

where G_m is the shear modulus of soil or rock medium, B is the width of the structure, P is the force required to cause a unit racking deflection of a rectangular frame structure, and H is the height of the tunnel as illustrated in Fig. 14. For a rectangular frame with an arbitrary configuration, the flexibility ratio can be determined by

performing a simple frame analysis; even for simple one-barrel frames, no computer analysis is needed.

The racking ratio (R) is the ratio structure racking distortion to the free-field ground distortion:

$$R = \frac{\Delta_{\text{structure}}}{\Delta_{\text{free-field}}}$$

NCHRP 611 (Anderson et al. 2008) developed a relationship between the racking ratio (R) of rectangular conduits and the flexibility ratio (F), whereby

$$R = \frac{2F}{1 + F}$$

Hashash et al. (2010) describes the procedure to be used for performing 2D pseudo-static racking analysis of rectangular tunnels (Fig. 15). In this type of analysis, the soil is assumed to be massless and the section deforms in pure shear. In a first step, Fig. 15a, the free-field racking deformation time history is computed from 1D site response analyses using hazard-compatible ground motion time histories.

Seismic Design of Tunnels, Fig. 15 2D pseudo-static numerical analysis (Hashash et al. 2010)

To perform the 2D numerical analysis, the second step (Fig. 15b) is to define the elastic properties of a uniform soil medium as the average strain-compatible elastic properties of the selected soil layers (Anderson et al. 2008). As recommended in Hashash et al. (2010), layers

1–3 m above and below the structure should be included. Shear modulus values can be selected using the strain-compatible shear wave velocities from site response analysis in the selected layers, from which the average shear modulus over the selected layers can be calculated. In this step, the

structural member properties are needed: E (stiffness), I (moment of inertia), and A (cross-sectional area).

Finally, in a 2D numerical analysis, the lateral displacement (d_{im}) time histories obtained from 1D site response analysis are applied at the left, right and top boundaries of the model to impose the free-field racking calculated in the first step on the model, as shown in Fig. 15c. With the numerical analysis, the soil medium will transmit shearing deformations to the box structure and the box racking deformation time history can be obtained. This is used to obtain the racking ratio (R).

Two-dimensional pseudo-static numerical analyses can be a very useful tool, but they have some limitations. The ground surface shear displacements for shallow box structures cannot be transmitted uniformly. The model can be artificially extended to address this problem. Racking deformations are assumed to vary uniformly over the height of the box structure. The response of individual layers is not represented. This becomes a problem when layers with very different stiffness are part of the soil profile.

Dynamic Soil-Structure Interaction

The complex soil-structure interaction of underground structures during seismic loading can be simulated using numerical analysis tools which include lumped mass/stiffness methods and finite-element/difference methods.

Lumped mass/stiffness methods are useful to analyze the 3D behavior of a tunnel lining in a simplified manner. Many parameters for the springs that represent the structure stiffness and the soil stiffness must be defined to have a realistic model.

In finite-element/difference models, the tunnel structure is discretized and the soil surrounding the tunnel can be either discretized or represented by springs. 2D and 3D models can also be used to analyze the inelastic sections of the tunnel cross section. Discrete element models are useful when weak planes in the soil profile exist, since in this method the soil/rock mass is represented by an

assemblage of distinct blocks (rigid or deformable) with a prescribed constitutive relationship.

One of the advantages of these dynamic soil-structure interaction analyses is that the soil layers are modeled to reflect the idealized site stratigraphy; each soil layer can be either modeled as a linear elastic material with strain-compatible shear modulus and damping values or characterized via soil constitutive models that represent soil nonlinearity and hysteretic response at small strains. However, the use of the nonlinear constitutive models requires careful selection of input parameters and thus more advanced testing to define those input parameters. The nonlinear behavior and the frequency content of the free-field environment contribute to the structural racking behavior.

Hashash et al. (2010) provides a simplified 2D dynamic soil-structure interaction procedure that makes computational effort manageable for design purposes of transverse response of rectangular tunnels. The first step is to perform a 1D site response analysis to obtain the acceleration and displacement time history throughout the soil profile and then obtain the strain-compatible shear wave velocities and damping ratios for the 2D model layers.

The numerical analysis involves applying the displacement time history at the model base, then propagating the ground motion through the soil to simulate the soil-box interaction. The displacement time histories must be obtained at four monitored points, as shown in Fig. 16, to calculate the relative box displacement $\Delta_{box} = \max[abs(\delta_{h,C} - \delta_{h,D})]$ and the free-field relative displacement $\Delta_{ff} = \max[abs(\delta_{h,A} - \delta_{h,B})]$ to then calculate the racking ratio $R = \frac{\Delta_{box}}{\Delta_{ff}}$. The complete soil profile does not need to be included; a limited thickness of soil that captures the characteristics of wave propagation is sufficient. In the dynamic soil-structure analysis, the soil profile represented in the analysis reflects the actual soil profile, as there is no need to use an average soil layer needed in pseudo-static analyses.

Seismic Design of Tunnels, Fig. 16 2D dynamic soil-structure interaction (Hashash et al. 2010)

Comparison of Pseudo-static and Dynamic Racking Soil-Structure Interaction Analyses

Hashash et al. (2010) performed a series of pseudo-static and dynamic soil-structure interaction analyses of single- and double-box structures in stiff and soft soil profiles using equivalent linear and nonlinear site response analysis with 14 ground motion time histories. The results are shown in Fig. 17. The results of the study found that for $F < 1$ the dynamic analysis and pseudo-static analysis appear to be quite similar and slightly above NCHRP 611 (Anderson et al. 2008). For $4 < F < 9$, the dynamic results show more scatter and higher racking ratios compared to pseudo-static results, both above NCHRP611 (Anderson et al. 2008). Dynamic analyses for $10 < F < 13$ show slightly lower racking ratios than pseudo-static analysis, both below NCHRP611 (Anderson et al. 2008). Some of the main conclusions from Hashash et al. (2010) are: (a) numerical approaches provide results and trends that are consistent with results obtained from simplified closed-form solutions, (b) there is a need to account for variability in the input ground motions and site response analysis methods as they affect the flexibility ratio (F), and (c) dynamic analyses must be

performed to verify and supplement the results of pseudo-static soil-structure interaction.

Performance Evaluation for Immersed-Tube Tunnels

Pseudo-static longitudinal 3D models can be used to analyze axial and bending deformations in immersed-tube tunnels. In a lumped mass analysis approach, the tunnel lining is divided into individual segments with different masses and stiffnesses. The masses are then connected by springs that represent the axial, shear, and bending stiffness of the tunnel as shown in Fig. 18 (Hashash et al. 1998). Free-field displacement time histories that consider effects of wave passage/phase shift and incoherence are calculated at selected locations along the tunnel's length. The computed free-field displacement time histories are then applied at the ends of springs to represent soil-tunnel interaction in a quasi-static analysis. If a dynamic analysis is needed, appropriate damping factors need to be incorporated into the structure as well as springs to represent the soil.

Recent work from Anastasopoulos et al. (2007) focuses on nonlinear response to

Seismic Design of Tunnels, Fig. 17 Results from comparison of 2D pseudo-static and dynamic numerical analyses (Hashash et al. 2010)

Seismic Design of Tunnels, Fig. 18 3D model for global response of immersed-tube tunnel (Hashash et al. 1998)

strong seismic shaking of deep immersed tunnels (≈ 70 m). The free-field acceleration time histories are computed at the base of the tunnel through 1D wave propagation analysis using equivalent linear and nonlinear analyses. The computed free-field acceleration time histories are then imposed on the supports of the tunnel in the form of excitation. The tunnel is modeled as a multi-segment beam connected to the ground through calibrated springs, dashpots, and sliders. Wave passage effects are taken into account using Eurocode 8 (EC8 2002); however, the geometric incoherence was not considered because it did not make a difference when added to wave passage. The soil is assumed to be uniform along the tunnel.

A finite-element analysis is used to perform a nonlinear dynamic transient analysis of the tunnel. Tunnel segments are modeled using beam elements that take into account shear rigidity. The joints are modeled with nonlinear hyperelastic elements. The bored tunnels at the end of both segments are incorporated in the analysis as beams on viscoelastic foundation. Influence of segment length and joint properties was then investigated parametrically.

The results from Anastasopoulos et al. (2007) show that seismic response of immersed tunnel correlates better with PGV than PGA consistent with prior studies. There are some key conclusions applicable to immersed tunneling projects. First, a properly designed immersed tunnel can resist near-fault soil-amplified excitation with a PGA as large as 0.6 g and PGV as large as 80 m/s and containing long period pulses. Also, the net tension and excessive compression between segments can be avoided by suitable design of joint

gaskets and relatively small segment lengths. However, it is important to note that this study did not examine the heterogeneous nature of the soil conditions and ground motion incoherency and did not investigate the time-dependent stress relaxation on the rubber gasket or the effect of tectonic displacements from fault rupturing.

Additional Seismic Performance Issues

A number of additional items must be considered when evaluating the seismic performance of box structures. The detailed treatment of all these items is beyond the scope of this document, but a brief overview of some of them is presented.

Response to Vertical Ground Shaking

Significant vertical ground motions often due to near-fault effects can impose vertical loads on the roof of box structures. Figure 19 shows a schematic of the vertical loading on relatively shallow box structure (Hashash et al. 2010). Two types of analyses can be performed to assess the vertical loads. The vertical acceleration near the ground surface can be estimated as part of the seismic hazard analysis and then be used to compute pseudo-static inertial load of the soil on the tunnel roof. Alternatively, 2D dynamic soil-structure interaction analysis representing both the underground structure and the soil can be performed to compute the vertical inertial loading on the roof. There remain significant uncertainties in selecting appropriate soil properties for propagating vertical ground motion in such a model.

Seismic Design of Tunnels, Fig. 19 Vertical ground shaking effects (Hashash et al. 2010)

Interaction of Temporary and Permanent Structures

Braced excavations are used when space is needed to construct a shallow underground structure. Temporary excavations in highly seismic urban areas are also being seismically designed though for a lower level of seismic shaking than a permanent structure. Dynamic soil-structure interaction analyses are preferable to analyze racking in temporary structures, because it allows the dynamic load increments and levels of deformation on the temporary system to be estimated without significant simplifications.

It is customary to neglect the contribution of the temporary shoring wall on the permanent tunnel box. This is based on the assumption that the presence of the temporary walls will enhance the performance of the system and neglecting it is prudent. The effect of the presence of shoring walls on the seismic response of permanent box structures was studied in Hashash et al. (2010). For many projects only a few feet of the top of shoring is system is cut off after completion of the box construction while the rest of the wall remains in place. The study analyzed a single box surrounded by soft clay using both 2D pseudo-static and dynamic methodologies, as discussed earlier. Three cases were considered in Fig. 20a.

Figure 20b shows that modeling the shoring wall over the height of the structure only slightly

reduces the racking ratio of the tunnel structure, and hence neglecting the presence of the temporary walls is acceptable. An increase between 15 % and 20 % in the racking ratios is estimated when the temporary shoring wall is modeled above and below the permanent structure. The shoring walls act as extended wings, transferring soil loads to the structure from above and below the structure and therefore creating more racking deformations (Hashash et al. 2010). Therefore, neglecting the contribution of the shoring walls in this case will lead to underestimating of the racking deformation and is thus not advisable.

Impact of Superstructure and Adjacent Structures

Shallow underground structures for public transportation are a key component of sustainable cities. In dense urban environments, underground structures are built in close proximity to high-rise building foundations. Tall buildings have the potential to change the ground motions in the foundation soil and therefore transmit significant forces and base shear to adjacent underground structures. It is therefore important to evaluate the impact of transmitted forces from the superstructure to the soil to the underground structure under earthquake loading.

If aboveground structures are built over existing underground structures, the interaction between the structures must be evaluated.

Seismic Design of Tunnels, Fig. 20 Effect of shoring walls on permanent structures (Hashash et al. 2010)

The global system performance can be evaluated by means of a numerical analysis of seismic soil-box-structure interaction.

A related item is that the placement of wide box structures in deep excavations in soft soils may lead to significant changes in the soil properties beneath the structure. The influence of those changes on the long-term dynamic response of the structure should be taken into account (Hashash et al. 2010).

Tunnel Joints: Portals, Stations, and Tunnel Segments

Stiffness differences in the tunnel structure may generate differential movements and stress concentration. Some examples include tunnel-building or tunnel-station connections, tunnel

junctions, tunnels crossing distinct geologic media, and local restraints of any type (Hashash et al. 2001).

The most common solution to these interface problems is the use of flexible joints. The first step in the design process is to use closed-form solutions or numerical analyses to determine the required allowable rotation and differential movements in the longitudinal, transverse directions. The joints also must be designed to support static and dynamic earth and water loads before and during the earthquake while remaining watertight. If a continuous design is implemented, very large forces and moments are likely to be generated (Hashash et al. 2001).

Tunnel portals and vent structures have part of their structure above ground; therefore, the

Seismic Design of Tunnels, Fig. 21 FEM lining models for trapezoidal and rectangular geometric configurations boundary conditions (Kramer et al. 2007)

Seismic Design of Tunnels, Fig. 22 Details of mesh development and boundary conditions (Kramer et al. 2007)

seismic design should account for inertial effects or potential pounding. It is always preferable that those structures are isolated from the tunnel through flexible joints (Hashash et al. 2001).

For soil-rock transitions, it is recommended that the tunnel not be cast directly against the rock. Instead, there should be some over-excavation filled with soil or aggregate. If that is not possible in bored tunnels, then a flexible lining can be installed (Hashash et al. 2001).

Precast Tunnel Lining

When a tunneling machine is used to excavate a tunnel, the lining usually is erected in segments. Single pass precast concrete segmental lining systems are often employed. The segment joint

connections must therefore be designed to accommodate anticipated deformations. The joint behavior can be kept elastic or allow inelasticity if proper detailing is performed. Numerical analyses are often used to evaluate the seismic performance of segmental lining. Kramer et al. (2007) performed 3D finite-element analyses, Fig. 21, to compute radial and circumferential joint behavior during seismic ovaling and wave propagation for the Silicon Valley Rapid Transit (SVRT) Project in San Jose, California. These analyses incorporate inelastic constitutive soil behavior, cracked concrete properties, and no-tension, frictional segment joint surfaces (Fig. 22). Kramer et al. (2007) provide guidelines for precast lining design in high seismicity zones.

Seismic Retrofit of Existing Facilities

When considering seismic retrofit of an existing tunnel structure, the retrofit strategy depends on the structure damage mode. If there is a gross stability problem, the seismic retrofit strategies involve strengthening the structure itself or the surrounding geologic materials.

One concern for a circular tunnel is the contact quality between the liner and the surrounding geologic media. Strengthening this interface includes replacing the lining, increasing the lining thickness by adding reinforced concrete, or adding reinforcing bars or internal steel liner. Increasing lining thickness is not always a good solution, as it tends to attract more load. Methods that increase ductility as well as strength are more effective (Power et al. 1996). Adding circumferential joints along the tunnel axis can also reduce the stresses and strains induced by longitudinal propagating waves. However, the value of adding joints must be weighed against the expected performance of the liner without joints. It is important to verify in the retrofit design that there will be no additional water leakage and that the joints will not become weak spots (Power et al. 1996).

In cut-and-cover structures, some seismic retrofit strategies include increasing ductility of reinforced concrete lining, adding confinement at existing columns, and adding steel plate jackets at joints.

Summary

The performance of the underground facilities during recent seismic events showed that the underground structures have suffered appreciably less damage than surface structures. However, the failure of even one of these underground structures can be detrimental to the proper post-earthquake operation of a tunnel network in urban areas. Thus, evaluation of underground structures to seismic shaking is necessary.

A performance-based approach is recommended for seismic evaluation of underground structures. Underground structures seismic response is controlled by the deformation of the soil or rock medium in which they are embedded and their

seismic evaluation is different from aboveground structures.

Seismic evaluation of underground structures includes evaluation for permanent and transient ground deformations. Pseudo-static and dynamic analysis approaches can be used to estimate the deformation of underground structures due to transient ground deformations and are presented.

Additional seismic design issues were discussed, including vertical ground shaking and response, interaction of temporary and permanent structures, impact of superstructure and adjacent structures, tunnel joints, and seismic retrofit of existing facilities.

Introduction

Maintaining the integrity of waste containment systems subject to seismic loading is not only important with respect to protecting human health and the environment from wastes and waste by-products, it is also important with respect to the availability of facilities essential for post-earthquake recovery, i.e., of landfills for proper disposal of the large volumes of earthquake-generated waste. Important considerations in the seismic design of waste containment systems include the response of the waste mass itself to seismic excitation, the stability of the waste mass (including its foundation), and the integrity of the engineered components of the waste containment system. Engineered components of waste containment systems include base and side-slope liner (barrier) systems, leachate and gas collection and removal systems, and final cover systems. Liner and cover systems include both natural soil and geosynthetic elements that serve as barriers to advective transport

of liquids and gas, as drainage layers for landfill leachate and surface water infiltration, and as protection for other components of the waste containment system. Geosynthetic waste containment system elements, including geomembrane and geosynthetic clay liner (GCL) barrier layers, geonet drainage layers, and geotextile filter, separation, and cushion (geomembrane protection) layers, are typically only found in containment systems constructed within the last 25 years, appearing with increasing frequency over that time span.

Figure 1 illustrates the components of municipal solid waste (MSW) landfill waste containment systems. MSW landfills are by far the most common type of engineered waste containment system, followed (with respect to frequency of occurrence) by cover systems (caps) for uncontrolled dumps and hazardous waste sites and then by hazardous waste landfills. Caps and containment systems for hazardous waste landfills employ similar elements to MSW landfills. The performance of ancillary facilities at a waste disposal site subject to seismic loading, including leachate and gas treatment facilities, surface water control systems, access roadways, and landfill monitoring systems, is also an important consideration but will not be addressed herein.

Following a brief review of the performance of landfills in earthquakes, this entry summarizes the state of knowledge on waste mass seismic response and the properties of the waste and geosynthetic materials relevant to seismic analysis and design. Current approaches to the seismic design of landfills are then discussed, culminating in a discussion of the value of performance-based seismic design for these important facilities.

Seismic Performance of Waste Containment Systems

In general, the seismic performance of waste containment systems subject to strong ground motion from earthquakes has been acceptable, i.e., has not resulted in a harmful discharge of waste or waste by-products to the environment.

Seismic Design of Waste Containment Systems, Fig. 1 Containment system components for modern (*left*) and older (*right*) landfills (Kavazanjian et al. 1998)

In the epicentral region of the 1989 M 6.9 Loma Prieta earthquake, several MSW landfills with 2H:1V slopes rising up to 60 m above grade withstood earthquake motions with peak ground accelerations estimated to be on the order of 0.6 g with only minor cracking in the soil cover, e.g., observed cracks on the order of a 50 mm or less (Buranek and Prasad 1991; Johnson et al. 1991; Orr and Finch 1990). However, there were observations of more significant cracking in the soil cover on the very steep north slope of the Operating Industries, Inc. (OII) Landfill (average inclination, 1.5H:1V; maximum inclination, 1.3H:1V) in the 1987 M 6.1 Whittier Narrows earthquake and the 1994 M 6.7 Northridge earthquake when they were subject to peak ground accelerations estimated to be less than half the 0.6 g level experienced by landfills in the Loma Prieta event (Kavazanjian et al. 2013b; Matasovic et al. 1998). Furthermore, neither the

OII Landfill nor any of the landfills subject to strong ground shaking in the Loma Prieta earthquake employed geosynthetic containment system elements (Kavazanjian et al. 2013b; Matasovic et al. 1998). Tensile rupture of a geomembrane barrier layer was observed at two separate locations at the Chiquita Canyon Landfill in the Northridge earthquake, one location at the crest of a lined side slope and a second location near the crest of a lined side slope (EMCON 1994). Figure 2a shows the cover soil cracking observed at the OII Landfill, and Fig. 2b shows one of the geomembrane tears observed at the Chiquita Canyon Landfill following the Northridge earthquake.

Geosynthetic waste containment system elements are of particular concern with respect to seismic loading because they create the potential for planes of weakness along which slippage and instability can occur (due to a relatively low

Seismic Design of Waste Containment Systems, Fig. 2 Damage to landfills observed following the Northridge earthquake: (a) cracking in soil cover on the

benches of the OII Landfill (Courtesy of Raymond B. Seed); (b) tear in the side-slope liner at the Chiquita Canyon Landfill (Courtesy of Robert M. Koerner)

interface or in-plane shear resistance) and because of their potential for tensile rupture which could result in breaching of barrier, filter, and protective layers and disruption of drainage layers. Stability failures of landfills have occurred under static loading due to the low interface shear strength of a geosynthetic waste containment system element (Koerner and Soong 2000; Mitchell et al. 1990; Seed et al. 1990) and the tensile rupture of the side-slope geomembranes at the Chiquita Canyon Landfill were cited previously. Furthermore, there are no case histories of cover systems with geomembrane elements subject to free-field ground motions in excess of 0.2 g, and cover systems are of particular concern due to the potential for amplification of seismic motions by the waste mass. There is also a potential for hidden damage to containment system elements beneath the surface of the landfill, where damage cannot be directly observed or readily detected by the monitoring systems employed in current practice.

Waste Mass Seismic Response

Overview: The seismic response of the waste mass is an important consideration in waste containment system seismic design as it controls the loading on the containment system elements as well as the global stability of the waste mass. Because there is often a significant impedance contrast between the waste mass and the underlying foundation material (soil or rock), landfill seismic response is susceptible to amplification of free-field motions. Amplification of earthquake ground motions is reported to have occurred at the one landfill at which strong ground motions have been recorded to date, OII Landfill (Kavazanjian et al. 2013b), and Bray and Rathje (1998) have conducted analyses suggesting that the amplification potential of municipal solid waste landfills is similar to the amplification reported by Harder (1991) between the base and crest of earth dams in the transverse direction. Figure 3 compares the amplification of peak ground acceleration from the base to the

Seismic Design of Waste Containment Systems,

Fig. 3 Amplification of peak ground acceleration at the OII Landfill in the Northridge earthquake (Kavazanjian et al. 2013b)

crest of the OII Landfill (as determined by back analysis) to the amplification of the transverse peak ground acceleration from the base to the crest of earth dams as reported by Harder (1991).

Waste Properties: Seismic response of a waste mass is controlled by waste mass properties, the waste thickness, and the impedance contrast between the base of the landfill and the waste mass (which depends upon the properties of the waste mass and the underlying foundation material) as well as the characteristics of the free-field ground motion. For landfills with geosynthetic elements in the liner and cover system, slip along the interface of a geosynthetic element may also affect the seismic response. However, slip at geosynthetic interfaces is usually ignored in practice when evaluating landfill seismic response. Analyses in which the potential for slip at the interface is ignored are termed “decoupled” analyses as landfill seismic response is decoupled from the geosynthetic interface behavior and potential displacement at the interface. A decoupled analysis is generally considered conservative with respect to predicting landfill seismic performance, though there are relatively rare situations where this has been shown not to be the case (Bray and Rathje 1998).

Most seismic response analyses in landfill practice are conducted using the equivalent linear method. Waste mass properties of importance in an equivalent linear seismic response analysis include the waste total unit weight (or mass density), the small-strain shear modulus, and equivalent linear shear modulus reduction and damping curves. Poisson’s ratio may also be of interest if two-dimensional equivalent linear response analyses are to be conducted. Small strain shear modulus is generally established based upon shear wave velocity and unit weight or mass density. Waste mass shear strength and the interface shear strength of geosynthetic elements (or in the case of a geosynthetic clay liner, the in-plane shear strength) are essential properties in seismic analysis of waste containment systems for waste mass stability and cover system assessments. The properties of natural soil materials used in landfill construction are also important in a landfill seismic stability assessment but are not discussed herein.

Figure 4, from Zekkos et al. (2006), provides a family of typical unit weight profiles for MSW landfills that depend upon the amount of cover soil and compaction effort provided by the landfill operator during waste placement. Due to difficulties in measuring the waste unit weight in the

Seismic Design of Waste Containment Systems,

Fig. 4 Typical MSW total unit weight vs. depth profiles (Zekkos et al. 2006)

field, Fig. 4 or some other relationship for typical unit values is usually used in landfill seismic analysis and design rather than direct measurement, even for existing facilities.

Shear wave velocity and the small-strain modulus of MSW have been measured in the field and in the laboratory. Zekkos et al. (2008) and Yuan et al. (2011) report shear wave velocity and small-strain modulus values measured in laboratory testing of MSW reconstituted at three different ratios of refuse (MSW particles >20 mm, i.e., retained on a 20-mm sieve) to soil-sized (MSW particles <20 mm, i.e., passing a 20-mm sieve) material (note that these investigators used the same MSW and same composition ratios but different laboratory devices). However, unlike unit weight, waste mass shear wave velocity is readily measured in the field, e.g., using noninvasive surface wave techniques. Field data is more reliable than laboratory testing on reconstituted specimens, and case histories of site-specific shear wave velocity measurements for landfills are being reported in the literature with increasing frequency. Figure 5 provides a summary of shear wave velocity profiles for MSW landfills worldwide as compiled by Ramaiah (2013).

Equivalent linear shear modulus reduction and damping curves for MSW are available from

three sources: (1) from back analysis of strong ground motion records from the OII Landfill alone (e.g., Idriss et al. 1995), in some cases supplemented with cyclic laboratory testing of waste (Matasovic and Kavazanjian 1998); (2) from large-diameter cyclic triaxial testing by Zekkos et al. (2008) on reconstituted waste specimens from the Tri Cities Landfill for three different composition ratios; and (3) from large-scale laboratory simple shear testing by Yuan et al. (2011) on reconstituted waste specimens from the Tri Cities Landfill for the same three composition ratios employed by Zekkos et al. (2008). Figure 6 presents the equivalent linear shear modulus reduction (Fig. 6a) and damping (Fig. 6b) curves from Zekkos et al. (2008) from large-scale triaxial testing, termed the UCB data, and from Yuan et al. (2011) from large-scale simple shear testing, termed the ASU data. These two data sets are relatively consistent with each other and with the OII field data and represent the best available information on these property relationship.

Poisson's ratio values for MSW have been derived from field measurements of shear and compressional wave velocity at the OII Landfill (Matasovic and Kavazanjian 1998) and from laboratory measurements of axial and radial strain (Zekkos 2005). Poisson's ratio can also be

Seismic Design of Waste Containment Systems, Fig. 5 Shear wave velocity at MSW landfills worldwide (Ramaiah 2013)

Seismic Design of Waste Containment Systems,

Fig. 6 Equivalent linear property relationships for waste specimens reconstituted at different composition ratios (Yuan et al. 2011): (a) shear modulus reduction; (b) damping

inferred from the field measurements of the lateral earth pressure at rest in MSW reported by Dixon et al. (1999). The data on Poisson's ratio from these studies is scattered, both within and among the studies, but it appears that values on the order of 0.2–0.4 are appropriate for unsaturated MSW.

Due to difficulties associated with conventional laboratory and field testing, studies of MSW shear strength have employed back

analyses of landfill failures under static loading to develop shear strength envelopes. Kavazanjian et al. (1996) employed back analysis of both landfill failures and steep stable landfill slopes to develop a bilinear strength envelope in which MSW was assigned a cohesion of 25 kPa at low normal stresses and a friction angle of 33° at higher confining pressures. Based upon back analyses of failed landfill slopes, Eid et al. (2000) proposed that typical MSW shear strength could

be characterized by a linear failure envelope with a friction angle of 35° and a cohesion intercept and that the lower- and upper-bound shear strength should be characterized using zero and 50-kPa cohesion, respectively. Based upon laboratory triaxial and direct testing on relatively large-sized specimens (e.g., 150 mm-diameter triaxial specimens), Bray et al. (2009) suggested that MSW shear strength was dependent on the normal stress and characterized by a cohesion of 15 kPa and a friction angle that was equal to 36° at a normal stress less than or equal to one atmosphere and that decreased by 5° for every log cycle of normal stress. Both Bray et al. (2009) and Kavazanjian et al. (2013b) have noted the anisotropic structure and shear strength of MSW, with the strengths reported above applicable to the horizontal plane, the weakest plane in a waste mass due to the preferred alignment of the long axes of waste constituents in this direction, and with substantially greater shear strength on non-horizontal planes that cut across the long axes of the constituents. Based upon analysis of landfill performance in the Northridge earthquake, Augello et al. (1995) suggested that the shear strength of MSW subject to seismic loading was greater than the static strength. Bray et al. (2009) suggest that the dynamic shear strength of MSW is at least 20 % greater than the static shear strength. However, in most seismic evaluations, the static shear strength has been found to be sufficient to demonstrate landfill seismic stability.

The data on material properties for waste materials other than typical MSW is rather sparse. Hazardous waste in modern landfills is generally stabilized and containerized prior to placement in a landfill. The containers are then stacked and backfilled with soil. In older hazardous waste landfills, the waste may have been containerized, typically in partially filled steel drums, without stabilization. Cone penetrometer testing at a 20–30-year-old hazardous waste landfill where the waste was placed in partially filled steel drums without stabilization showed no evidence that the drums were still intact or of voids (as would be expected at the top of a partially filled drum) (Matasovic et al. 2005).

Furthermore, hazardous waste disposed of in landfills is often a hazardous material (e.g., pesticide residue, organic solvents) or mixed waste (e.g., potentially radioactive construction and demolition debris) in a soil matrix. Hence, it is common to assume that the properties of the waste mass at a hazardous waste site are the same as the properties of the backfill soil (or of the native soil at a hazardous material spill site) (Kavazanjian and Matasovic 2001).

Geosynthetic Properties: The interface shear strength of geosynthetic materials and the in-plane internal strength of GCLs can vary widely, depending upon the type of geosynthetic material, the nature of the material in contact with the geosynthetic material, and for GCLs the internal reinforcement and moisture content (Zornberg et al. 2005; McCartney et al. 2009). Furthermore, many geosynthetic materials have significantly different peak and large-displacement shear strengths.

Hydrated unreinforced or poorly reinforced GCLs can have extremely low in-plane shear strengths, in some cases as low as the hydrated strength of their sodium bentonite core (e.g., a friction angle, ϕ , equal to 4° at high normal stresses). However, such materials are rarely used in landfill construction. Hydrated reinforced GCLs can have a substantial peak internal shear resistance, sometimes in excess of $\phi = 30^\circ$, and still maintain a relatively high strength when subject to large deformation (i.e., $\phi > 15^\circ$), depending on the quality of the reinforcement.

Smooth geomembranes in contact with cohesive soils (e.g., compacted clay) can have very low shear strength ($\phi =$ on the order of 10°), but textured geomembranes can provide substantially higher interface strengths, even when subject to a large displacement (ϕ sometimes on the order of 16 – 20° for the large displacements). Granular materials in contact with smooth geomembranes may have an interface strength exceeding 70 % of the shear strength of the granular soil, while the shear strength of a granular material in contact with a textured geomembrane may approach the shear strength of the soil. Nonwoven geotextile placed against a smooth geomembrane will have a relatively low shear

strength but can have a peak interface strength exceeding that of most natural soils if placed against a textured geomembrane. Woven geotextile placed against a smooth geomembrane will typically have a higher interface strength than a nonwoven geotextile against a smooth geomembrane. Woven geotextiles are not typically placed against textured geomembranes. Geonets placed upon a geomembrane (textured or smooth) may have a low interface strength ($\phi = 10^\circ$) but can be heat bonded to a nonwoven geotextile and then placed against the geomembrane if a higher interface strength is desired.

Minimum required interface strengths are typically established by design analyses and then specified in design documents. Laboratory testing is often conducted during design to demonstrate that the required strengths are achievable with available materials. The geosynthetic materials used in construction are then generally subject to conformance testing prior to the start of construction and to quality assurance testing during construction to demonstrate that the specific materials used in construction can provide the specified interface shear strength.

Other geosynthetic properties of importance to seismic design include the tensile strength and the strain at yield and at failure of the geosynthetic elements of the containment system. For advanced analyses, the shear and axial stiffness of geosynthetic material elements may be required.

Design Analyses

Decoupled Analysis: Most seismic analyses of landfill systems conducted in practice today employ a decoupled approach in which the response of the landfill to the seismic loading is considered separately from integrity assessments for the waste mass and containment system components. The seismic response analysis is conducted assuming that the containment system components and waste mass maintain their integrity, that there is no relative displacement at geosynthetic interfaces, and that no instabilities develop. The most common type

of seismic response analysis is a one-dimensional equivalent linear analysis of a representative column or columns for the waste mass. For important projects, nonlinear one-dimensional analysis and two-dimensional equivalent linear analyses are sometimes performed. Nonlinear two-dimensional analyses are primarily used for research purposes. The integrity assessment is usually based upon the calculated seismic response, permanent seismic displacement calculated in a Newmark-type seismic displacement analysis, and empirical rules on allowable displacement for the various elements of the containment system. The Newmark displacement analysis is typically conducted using shear stress time histories from the seismic response analysis and a yield acceleration calculated using conventional limit equilibrium analysis. The standard of practice is to use the large-displacement static shear strength of any interface engaged in the limit equilibrium analysis. If more than one interface is aligned with a slip surface engaged in the limit equilibrium analysis, the large-displacement static strength of the interface with the lowest static peak strength is employed.

Due to the interrelationship between the yield acceleration, shear stress time history, and calculated seismic displacement, multiple potential sliding mechanisms must be checked in a landfill seismic stability assessment. Potential sliding mechanisms include veneer failures of the landfill cover along interfaces with containment system elements (both geosynthetic and natural soil) and between the cover soil and the waste, circular surfaces through the waste mass and/or the foundation, and sliding block surfaces along planes of weakness in waste, including along interfaces with geosynthetic and natural soil containment system elements and other potential planes of weakness. Figure 7 provides an example of a landfill seismic stability analysis in which multiple potential sliding surfaces were evaluated (Kavazanjian et al. 2013b). In this case, the horizontal planes of weakness were continuous layers of daily and interim covers hypothesized to be present within the waste mass. The calculated seismic displacement on each of these failure surfaces is considered independently in the integrity assessment.

Seismic Design of Waste Containment Systems, Fig. 7 Potential sliding mechanisms assumed in seismic stability assessment for the OII Landfill: g-values

represent the peak average acceleration for each potential sliding mechanism (Kavazanjian et al. 2013b)

Due to the conservatism associated with the decoupled approach and the use of large-displacement static shear strength, the calculated permanent seismic displacement from this type of analysis is considered merely an index of seismic performance and not the expected permanent seismic displacement along the hypothesized sliding surface. A calculated seismic displacement of 150 mm or less is typically considered indicative of minimal permanent seismic displacement in the design earthquake, and calculated displacements of up to 1 m are considered indicative of limited displacement. Calculated displacements of greater than 1 m are considered indicative of the potential for large, possibly uncontrolled displacements in the design earthquake.

Table 1 summarizes typical values of acceptable calculated seismic displacement for non-geosynthetic components of landfill containment systems from a decoupled analysis, along with the anticipated duration for the interim and final repairs of these components. For the geosynthetic elements of waste containment systems, 150 mm of calculated displacement is generally considered to be indicative of no damage, and up to 3 m of displacement may be considered acceptable for geosynthetic elements in which

damage can be readily detected in a post-earthquake inspection and readily repaired. It should be noted that these general guidelines are based primarily upon back analyses of the performance of slopes, embankments, and landfills in earthquakes using conventional decoupled analysis. If a more sophisticated seismic analysis is conducted, e.g., a two-dimensional nonlinear coupled analysis of seismic response and displacement, these guidelines may not be appropriate, particularly with respect to damage to the geosynthetic elements of the containment system.

Coupled Analysis: Coupled analysis of landfill seismic response and waste containment system integrity is rare and complex due to difficulties in modeling slip at interfaces and geosynthetic element stress-strain behavior. Bray and Rathje (1998) developed a one-dimensional model for landfill response that included slip at the interface. Kavazanjian et al. (2012) describe a fully coupled two-dimensional model for performance-based seismic design of waste containment systems that accounts for both slip at an interface and geosynthetic element stress-strain behavior. The interface model allows for a post-peak decrease in the interface shear strength. Geosynthetic

Seismic Design of Waste Containment Systems, Table 1 MSW landfill seismic design criteria and performance standards for decoupled analysis (Kavazanjian et al 1998)

Cover system component	Design criteria and performance standard	Interim remediation to restore compliance	Repair to pre-earthquake condition
Final cover			
Soil monocover on side slopes	150 mm of soil deformation; partial failure contained on site	3 months to strip vegetation and regrade and recompact areas of cracking	12 months to restore vegetation
Landfill gas control			
Collection wells	Up to 25 % of wellheads broken	1 month to route headers around broken wellheads	12 months to repair/replace broken wellheads
Headers	Up to 25 % of header pipes cracked or broken	1 month to bypass broken header pipes	3 months to repair/replace broken headers
Vacuum pumps	Power loss; no structural damage	None required	1 month to restore off-site power
Leachate transmission pipes	Acceptable breakage of pipes with double containment	1 month to bypass broken pipes	3 months to repair broken pipes
Surface water management			
Conveyance systems (bench channels, down drains, culverts)	Cracking and up to 300 mm of displacement	2 months to completely restore surface pathways	9 months to replace/rebuild surface pathways
Sedimentation basin	Minor cracking of concrete	2 weeks to 1 month to patch the cracks	9 months to rebuild the basin (if needed)
Access roads	300 mm displacement (cracking)	2 months to patch the cracks	12 months for full repair

elements of the waste containment system are modeled as structural beam elements with zero moment of inertia (to allow for buckling) and with a parabolic stress–strain model, allowing for explicit calculation of forces and strains in the geosynthetic elements of the containment system. Parametric studies using this model suggest that in some cases the geosynthetic elements of a waste containment system may not sustain significant damage even though a decoupled Newmark analysis results in a calculated displacement of greater than 150 mm. In particular, when the interface shear strength on the top of a geosynthetic element is less than the interface shear strength on the bottom of the geosynthetic element and there are no irregularities (penetrations, seams) in the element, the interface may be able to sustain large sliding displacements without incurring damage to the geosynthetic element, i.e., without exceeding its

tensile strength. However, a back analysis of the geomembrane tears observed at two separate locations at the Chiquita Canyon Landfill (cited previously) has suggested that damage can occur to geosynthetic waste containment system elements when the calculated Newmark displacement is less than 150 mm and when there are irregularities in the containment system, e.g., due to strain concentrations around patches in the geomembrane at locations where coupons were removed for destructive testing as part of the construction quality assurance (CQA) program (Kavazanjian et al. 2013).

Performance-Based Design: Figure 8 illustrates the strain in the geomembrane for a landfill side-slope liner as predicted by the performance-based seismic design model described by Kavazanjian et al. (2012). While this model has yet to be fully validated, back analysis of the performance of the Chiquita Canyon Landfill in

Seismic Design of Waste Containment Systems,

Fig. 8 Strain induced in a side-slope liner system geomembrane by seismic loading (Kavazanjian et al. 2012)

the Northridge earthquake (Kavazanjian et al. 2013a) indicates that strains due to the anchoring of the geomembrane at the crest of the slope and strain concentration factors due to seams in the geomembrane (Giroud 2005) at locations where coupons were removed for CQA testing must be considered in order to predict the tears observed in the liner following the earthquake. These recent findings suggest that, at a minimum, new guidelines need to be developed for acceptable locations for removal of coupons for CQA testing and for minimizing other irregularities in the geosynthetic elements of the containment system. However, ultimately performance-based design using fully coupled models that consider interface and geosynthetic material behavior to explicitly predict strain and forces in geosynthetic elements of modern waste containment systems is likely to become the standard of practice, at least for critical facilities in areas of high seismicity.

Summary

Seismic design of waste containment systems is an important consideration with respect to both maintaining the protection afforded by the containment system for human health and the environment and providing safe and secure capacity for waste disposal during earthquake response and recovery operations. Important engineering considerations with respect to the seismic design of waste containment systems include the seismic

response of the waste mass and methods for evaluating the integrity of containment system components subject to seismic loading. Observations of landfill performance in earthquakes indicate that the waste mass may amplify free-field ground motions and that containment system elements, including geosynthetic liner system components and soil cover, are susceptible to earthquake-induced damage. Waste mass seismic response depends to a large extent upon the waste mass material properties, including the small-strain stiffness, strain-softening behavior, and internal damping in the waste. For landfills with geosynthetic liner and cover systems, the interface and in-plane shear strength of the geosynthetic components is also an important consideration with respect to seismic response. Most containment system performance analyses employed in engineering practice are decoupled analyses in which waste mass seismic response is calculated using the equivalent linear method and the performance of liner system components is assessed based upon the calculated seismic displacement from a Newmark-type analysis. The seismic performance of containment system components is then assessed based upon empirical rules for allowable calculated displacement. While more sophisticated fully coupled performance-based analyses in which the forces, strains, and displacements induced by the earthquake in containment system components are explicitly calculated are possible, such analyses have yet to make their way into engineering practice.

Introduction

Seismic stations record signals continuously; however, the main interest for the user is the recordings of seismic events. The events will normally be contained in a very small fraction of the actually recorded signal (Fig. 1).

As it is seen in this 24 h seismogram, there are only a few sections with real seismic events and a lot of other wiggles which is just noise. The more or less continuous noise seen throughout the seismogram is the earth's background noise (see below and Figs. 2 and 4). In the old days when all the signals were recorded on paper (on seismograms), the events were detected easily by eye, particularly for small local events with high-frequency content. This method is sometimes also used with today's digital recordings which can be displayed on screen or printed on paper. But the majority of event detection is done automatically, either in real time to limit the amount of data recorded or off-line when large data sets have been collected, e.g., from field experiments. Over the years a few simple and very many sophisticated algorithms have been developed to automatically detect a "real" signal in the presence of noise. Few, if any, have been developed that can beat the human eye, which still is used to evaluate the efficiency of the detector. The use of a trigger or a detector can have two purposes:

1. Determine the onset of real seismic events in a large data set. These onset times will be used for further processing.
2. Extract out the waveform time segments of a larger data set which contains seismic events, either in a field recorder to limit the amount of data recorded or to extract out just the useful events for processing.

In this entry, the most common event detection methods will be described. An overview of detection methods is found in Sharma et al. (2010).

Seismic Event Detection, Fig. 1 A seismogram for a 24 h period. Detected events are indicated with the name of the region where the earthquake occurred, D is

the distance from the station to the event in degrees, h is the depth of the earthquake, and M is the magnitude (Figure from www.okgeosurvey1.gov/seis/20011219.gif)

Seismic Event Detection, Fig. 2 Typical amplitude of the microseismic background noise as a function of period(s) (The data for the plot are taken from Brune and Oliver 1959)

Examples of Seismic Signals

Detecting real seismic events in a continuous data stream can be quite a challenge, particularly if there is nonstationary noise like noise from cars passing by or wind gusts and in some cases it is virtually impossible to distinguish between man-made noise and real seismic events.

In addition, there is an ever present so-called microseismic background noise (see Figs. 4 and 1). This noise is caused by standing waves in the ocean and wave action near the coasts. It is present all over the world, strong near the coast, and weaker far from the coast. It has a maximum amplitude at a period of about 4–6 s. Figure 2 shows a typical curve with the noise as a function or period.

Seismic events can have quite a range of appearances and frequency content depending on the type of seismic sensor used and the

Seismic Event Detection,

Fig. 3 Seismogram of a local event ($M = 1.5$) at 5 stations. Sensors are short period and the traces are not filtered. Each trace is auto scaled. The first arrival phase P and second arrival phase S are indicated. The epicentral distances (distance from the earthquake to the station measured along the surface) are given above the traces to the *right* (The figure is from Havskov and Ottemöller 2010)

Seismic Event Detection, Fig. 4 A magnitude 1.5 event recorded on a broadband station. The *top* trace is the original trace and the *bottom* trace has been filtered from 5 to 10 Hz

distance to the event and its magnitude. Essentially there are three types of seismic sensors: short-period measuring ground velocity (frequencies above 1 Hz), broadband measuring ground velocity (frequencies typically from 0.01 to 50 Hz), and accelerometers measuring ground acceleration from 0 to 100 Hz. Some examples will be given of seismic events.

Local small earthquake recorded with short-period sensors (Fig. 3). The signals are high frequency, and P- and S-phases are clearly seen although the P-phase is getting close to the noise level for station ASK.

Small event recorded on a broadband station (Fig. 4). The high background noise level, the

microseismic noise, is the harmonic signal dominating the record. It has a period of 4.5 s. A small high-frequency event will “drown” in this noise and can practically not be seen on the original record. By filtering the signal from 5 to 10 Hz, the local event is clearly seen. This illustrates that event triggering often will have to work on filtered traces. So how did humans detect this kind of event before digital recording? Simply by recording the signals in two different frequency bands, short period above 1 Hz and long period below 0.1 Hz, and thereby filtering out the noise around the microseismic peak (Fig. 2).

Distant event recorded on a broadband station (Fig. 5). This magnitude 6.2 event is recorded at

Seismic Event Detection,

Fig. 5 Recording of an earthquake at a large distance (4,200 km). The insert above left shows a zoom of the noise before the *P*

a distance 4,200 km. It is seen that a large distant event has much lower frequencies than small local events, partially due the source nature of earthquakes and partly due to filtering out the high frequencies along the path.

The unfiltered trace shows, before the *P*, the microseismic noise. For smaller events the *P* might drown in the noise. The microseismic noise is filtered away in the middle trace and the phases appear very clear. The bottom trace is filtered so the signal looks like it would have been recorded on a short-period seismograph. In this case a detector would not be able to find the true extent of the seismic event since the long-period *S*- and surface waves are not seen.

Volcanic events (Fig. 6). Volcanoes present a special problem since the signals from the events often are very emergent. Figure 6 shows the most common types.

The tectonic event is like any other earthquake and is easy to detect. The shallow events are very harmonic and monochromatic and of sufficient amplitude to be easy to detect. The surface event can be very difficult to detect automatically since it is very emergent and might be mistaken for noise. The harmonic tremor is a continuous series of harmonic events and cannot be detected.

Many events close in time: Figure 7 shows swarm activity of small earthquakes in a 24 h period. The human eye can easily detect the individual events while an automatic trigger would have problems with separating the events.

Seismic Event Detection, Fig. 6 Major types of seismic signals from volcanoes (From <http://vulcan.wr.usgs.gov/Images/Gif/Monitoring/Seismic/quakes.gif>)

Trigger Methods

A trigger or detector is an algorithm that checks the signal for variations that could indicate an event. There are several trigger algorithms available, some very sophisticated using neural networks (e.g., Romeo et al. 1995) and pattern recognition (e.g., Köhler et al. 2010). In the hands of an expert, they can significantly improve the event detections/false trigger ratio,

Seismic Event Detection, Fig. 7 Swarms of earthquakes. A 24 h record on 5 February 2013 of a temporary broadband station during the seismic swarm of Torreperegil (Southern Spain)

Seismic Event Detection,

Fig. 8 An example of level trigger. The plot shows a horizontal component of the accelerogram of a small local earthquake. The trigger level is marked with two horizontal lines. In this case the de-trigger level is the same as the trigger level. Usually the triggers of the three components are combined, and an event is declared if at least two or three channels are triggered within a given time window (e.g., 1 s)

particularly for a given type of seismic events. However, the sophisticated adjustments of operational parameters to the actual signal and seismic noise conditions, at each seismic site, which these triggers require, have often been proven unwieldy and subject to error. Hence, for practical purposes, only two types of triggers are widely used, the level trigger and the *STA/LTA* trigger (see below), and only those will be described here.

The level trigger: This trigger is also called the amplitude threshold trigger and simply searches for any amplitude exceeding a preset threshold. The start of the event is declared when this threshold is reached and the end of the event is declared when the level reaches the de-trigger level, usually smaller than the trigger level. When this type of trigger is installed in a recorder, that only shall record the real events, the recording window will be extended with a pre-event time before the trigger and a post-event time after the trigger (Fig. 8). This is to ensure that the whole event is recorded.

The level trigger has some obvious problems. If DC (a constant voltage) is present in the signal and not removed before triggering, it can prevent triggering or keep the instrument in continuous trigger mode. If no averaging or filtering is done,

the level trigger will also trigger on a single high value (a spike), which obviously is not a seismic signal.

This algorithm is often used in strong-motion seismic instruments (recording large ground accelerations), where high sensitivity is not an issue and where consequently man-made and natural seismic noise is not critical. The level trigger is now largely replaced by the *STA/LTA* trigger (see next section), since computer power no longer is an issue. However, many instruments still have the level option.

The short-term average – long-term average trigger (STA/LTA) is the most frequently used trigger algorithm. A single channel of seismic signal is typically processed as follows: The signal is band-pass filtered, and the absolute average *STA* (short-term average) over the *STA* time window is determined. Typically, the *STA* time window is 0.5 s for local earthquakes. A short *STA* time makes the trigger more sensitive to short-term variations in the signal, while a longer *STA* is better at averaging out short-term fluctuations and it can be compared to a low-pass filter. If there are spikes in the signal, a long *STA* must be used in order to average out the interference. This will of course reduce the sensitivity to short-lasting signals, but if a longer-lasting signal is the

objective, *STA* can be as long as the duration of the main P-wave train. The most common mistake in setting the *STA* is to use a too short value.

The same filtered signal is also used to calculate the *LTA* (long-term average) over the *LTA* time window, which is typically 50–500 s. Thus, *LTA* will give the long-term background signal level, while the *STA* will respond to short-term signal variations. The ratio between *STA* and *LTA* is constantly monitored, and once it exceeds a given threshold, the trigger level, the start of an event is declared for that trace. The *LTA* should be short enough to adapt to slow changes of the background noise and long enough to avoid reducing the sensitivity to triggering on low-amplitude emergent signals. This can be a problem with very emergent signal where the *STA* might increase fast enough to prevent triggering (see the surface event in Fig. 6). Since the natural background noise usually changes very slowly, it is generally better to use a too long than a too short *LTA* time. If *LTA* is not frozen during triggering (see next section), the *LTA* time must be at least as long as the event duration to prevent premature de-triggering. Using a too short *LTA* time combined with a high trigger ratio might even prevent triggering completely since the *LTA* is adjusted upward so fast that *STA/LTA* never exceeds the trigger ratio.

Once the event starts, the *LTA* is usually frozen, so that the reference level is not affected by the event signal. The end of the event is declared when the *STA/LTA* ratio reaches the de-trigger level. Trigger levels and de-trigger levels of 4.0 and 2.0, respectively, are typical values. In order to get the complete event, the recording will start pre-event time before the trigger time. Likewise, to avoid the truncation of the signal, recording continues some time after the de-triggering, the post-event time. The maximum time of recording can usually be limited by a maximum recording time setting, and it is also sometimes possible to discard triggers lasting less than a certain time, the minimum trigger time.

STA and *LTA* must be calculated on signals without a DC component in order to reflect the real signal. The DC is normally removed by

filtering, which is desirable also for other reasons (see below). The *STA/LTA* trigger algorithm is well suited to cope with fluctuations of natural seismic noise, which are slow in nature. It is less effective in situations where man-made or natural seismic noise of a bursting or spiky nature (e.g., wind gusts) is present. At sites with high, irregular seismic noise, the *STA/LTA* trigger usually does not function well, meaning there are too many false triggers.

A typical implementation will now be described. The trigger must be running continuously in the computer, so the *STA* and *LTA* values are calculated as running averages:

$$\begin{aligned} STA_i &= STA_{i-1} + \frac{|x_i| - STA_{i-1}}{NSTA} \\ LTA_i &= LTA_{i-1} + \frac{|x_i| - LTA_{i-1}}{NLTA} \\ R_i &= \frac{STA_i}{LTA_i} \end{aligned} \quad (1)$$

where x_i is the signal (filtered or unfiltered); *STA*, the short-term average; *LTA*, the long-term average; *R*, the *STA-LTA* ratio; and *NSTA* and *NLTA*, the number of points in the *STA* and *LTA* windows, respectively. In this case, x is the unfiltered signal. This works if the signal has no DC component, but if x has a large DC component, this will be transferred to the *STA* and *LTA* and they might be so large that *R* never reaches the trigger ratio.

There are two common variations of the trigger algorithm Eq. 1. One is to use the squared x_i instead of the absolute value. Using the squared x_i , makes the trigger more sensitive to changes. The other is the Allen trigger (Allen 1978), in which the absolute value of x_i is replaced by the characteristic function c_i . In a simplified form, c_i is calculated as

$$c_i = x_i^2 + k \cdot (x_i - x_{i-1})^2 \quad (2)$$

where k is a constant. The second term is proportional to the squared first time derivative of the signal. The characteristic function is sensitive to

Seismic Event Detection, Fig. 9 Below:

A spectrogram of the signal plotted above, with three local earthquakes closely spaced in time. It is apparent that the amplitude of high frequencies decays faster than lower frequencies after the first arrival of each event. The colors indicate spectral amplitudes

both amplitude variations and frequency changes.

All the above described trigger methods have in common that they are *not-looking-forward* algorithms, i.e., the present value of the trigger parameters depends only on present and past values of the signal. This makes them easy to implement with simple recursive, real-time operations.

If the seismic events are very close in time (Fig. 7), it is obvious that the STA/LTA would produce many failures. If one event is not finished before the next event starts, the first event would simply be prolonged so correct start times of events would only be obtained when a new trigger occurs after the previous has finished. A more sophisticated trigger might also monitor the frequency content of the signal. Since the end of the event usually has a lower-frequency content than the initial P-wave, this could be used to declare the start of a new event before the previous event is finished. This can be illustrated with a spectrogram which is a time-frequency representation of the spectral content of a signal. Figure 9 shows an example with three events occurring within 70 s.

A human analyst works in a quite different way: He detects an event looking at the entire record and evaluates the past, present, and subsequent values of the trace (or something like the envelope of it) to decide the presence of an event

and its onset time. So the human analyst would have no problem detecting the events in Fig. 7.

Figure 10 shows an example of how the algorithm STA/LTA works for the standard trigger using the absolute value.

The original signal is a small high-frequency earthquake with a medium-level microseismic background noise, which is reflected in the slow variations of the STA and more smoothed in the LTA. At about time 12 s, the ratio gets above the threshold of 3 (1. trigger). It immediately gets below again, but since the de-trigger ratio is 2, the trigger remains activated. In the above example, the LTA is frozen once an event has been declared, which can be seen from the flat LTA level. A few seconds after the de-triggering, the ratio again rises above the trigger level and remains in trigger state for about 1 s (2. trigger). This signal has a good signal-to-noise ratio, so why has the trigger not been activated much longer? The first reason is simply that the DC has not been removed before calculating STA and LTA. Since STA and LTA before triggering are about 220, the event will de-trigger when STA is 440 and the maximum ratio is 7 (Fig. 10 and Table 1). The DC of this signal is only 200 as compared to the maximum value of 3,400; yet if it is not removed, it will have a large influence on the trigger performance.

When the DC is removed, the figure corresponding to Fig. 10 will look almost the

Seismic Event Detection, Fig. 10 The seismic trigger. *Top* trace is the original signal; the second trace, the *STA*; the third trace, the *LTA*; and the last trace, the *STA/LTA* ratio. The *STA* window is 0.4 s and the *LTA* window is 50 s. The trigger ratio is 3 and the de-trigger ratio 2. All amplitudes are counts (the raw number generated by the recorder) (Figure from Havskov and Alguacil (2010))

Seismic Event Detection, Table 1 Effect of DC and filter on *STA*, *LTA*, and *STA/LTA*. The units of the numbers are in counts

	DC not removed	DC removed	Filtered 5–10 Hz
<i>STA</i> and <i>LTA</i> before trigger	220	40	3
Maximum <i>STA</i>	1,500	1,450	600
Maximum <i>STA/LTA</i>	7	36	200
Duration of trigger (s)	15	50	105

same, but since both noise, *STA* and *LTA*, are smaller due to the removal of the DC, *STA/LTA* will be much higher for the earthquake signal, and the event will remain in trigger state for 50 s instead of 15 s (Table 1). The performance can be further improved by filtering. The signal has a typical microseismic background noise superimposed, and this gives the main contribution to the *STA* and *LTA* before triggering. By using a band-pass filter from 5 to 10 Hz, the performance is further improved (Table 1) and the trigger lasts for 105 s.

So, the conclusion is that every trigger must have an adjustable band-pass filter in front of the trigger algorithm, which has both the function of removing the DC and making the trigger algorithm sensitive to the frequency band of interest.

This is particularly important with broadband seismometers, where small earthquake signals often are buried in dominant 0.2–0.3 Hz seismic noise and a trigger without a filter simply would not work except for the largest events (Fig. 4). Some recorders allow several trigger parameter sets to be used simultaneously. This is needed if, e.g., a broadband station has to trigger on micro-earthquakes, teleseismic P-waves, and surface waves which each requires separate filters, *STA*, and *LTA*.

For more detail of how to set and use *STA/LTA* triggers, see Trnkoczy, information sheet 8.1 in New Manual of Seismological Observatory Practice (NMSOP) (Bormann 2012).

Improved Triggering Using Several Stations, the Network Trigger

Whatever trigger method is used with single channels or single three-component stations, there is always likely to be quite a lot of false triggers, all depending on the local conditions and how sensitive the trigger has been set up. When several stations within a single network are processed together, the number of false triggers can be significantly reduced setting up a requirement of concurrent triggering. This means that for a network trigger to be declared, there must be a minimum number of triggers within a given time window, the array

Seismic Event Detection,
Fig. 11 A volcanic event recorded on an array of vertical sensors. The bottom trace (black) is the sum of the individual channels (color), once they have been time aligned using the P-wave relative propagation times. The improvement on the signal-to-noise ratio is apparent

propagation window. The array propagation window is calculated as the time the waves take to propagate across the network. If, e.g., the network is 100 km in diameter and assuming the case that triggering takes place on the S-waves only and the event is outside the network, then the array propagation window should be $100/V_s$ where V_s is the S-wave velocity. If some stations trigger on P and others on S, the array propagation window should be even larger by the S-P time so in general the array propagation time is set to a value larger than $100/V_s$. In case there is swarm activity (Fig. 7), a network trigger might not help a lot since the events come so close in time that it would be hard to associate events, that is, if the events are correctly triggered in the first place.

Triggering Using a Seismic Array

A seismic array consists of multiple sensors in a small enough area that signals are correlated, and the seismic array is therefore also sometimes called a seismic antenna.

The signal-to-noise ratio of a seismic signal is improved by summing the signals of each station in the array using a delay corresponding to ray travel time across the array so the signals get lined up. In this way the coherent seismic signal

will be enhanced and the supposedly incoherent noise will cancel out. Running a seismic trigger algorithm on the summed signal will therefore be more sensitive and more reliable than on any of the single stations. In a way this is similar to the network trigger where the same event must be present in all channels. An example is shown in Fig. 11.

Triggering Using Three Channels

Most seismic stations today have three channel sensors oriented vertically, north–south and east–west. As a first small improvement in the triggering, it can be required that all three channels trigger on the seismic event. Since external disturbances affect all three channels, this requirement might only improve the detection marginally. With three channels, it is possible to make a polarization analysis or in other words determine the particle motion of the ground (see Fig. 12).

For simplicity, the polarization is only shown in the north-vertical plane. It is seen that the P-wave is not polarized in the noise and highly polarized in the P-wave signal. By continuously calculating the degree of polarization, it is possible to distinguish a P-wave from background noise which would have no polarization.

Seismic Event Detection, Fig. 12 *Top:* the three components of ground velocity for a local earthquake. *Bottom:* the particle motion in the north-vertical plane at two different times as indicated on the figure. To the *left* is the analysis of the noise and to the *right* the analysis of the P-wave signal

This property has been used to improve the detection of P- and S-waves (Roberts et al. 1989; Withers et al. 1998).

Triggering Using a Known Waveform

Many seismic events have very similar waveforms if they originate from the same or nearby sites. This could also be the case for volcanic events even though they might not be from exactly the same area. A “known” waveform shape can then be used to detect unknown arrivals by cross correlating the known wavelet with the signal of unknown events. An example of similar events is seen in Fig. 13. Despite the large distances, the signal shapes are nearly identical for the two events.

The only trigger parameter would then be the minimum correlation needed to declare an event. Using this technique, it is often possible to detect events which otherwise could not be detected. When using a seismic array, this method is particularly powerful (Gibbons and Ringdal 2006).

Seismic Event Detection, Fig. 13 *Left:* the first couple of seconds of the P-waves for the two events occurring in the same area as recorded with three different stations.

The *top* trace event has magnitude 1.8 and the *bottom* trace event magnitude 1.6 (Figure from Havskov and Ottemöller (2010))

Summary

Today, huge quantities of continuous seismic data are recorded, and automatic detection of the seismic events is indispensable. Over the years very many algorithms have been developed to detect “real” seismic events; however the overall most used and reliable detectors are based on the standard STA/LTA method. Combined with a network trigger, this becomes a simple and robust event detector, in particular considering that the number of stations is continuously increasing so more use of the network trigger can be done, making the requirement for the single-channel detector less stringent.

Damage probability matrix; Fragility curve; Fragility surface; Limit state; Numerical simulation; Seismic capacity; Seismic demand; Uncertainty

Introduction

Seismic fragility can be defined as the proneness of a structural component or a system to fail to perform satisfactorily under a predefined limit state when subjected to an extensive range of seismic action. In accordance with the above definition, seismic fragility analysis can be regarded as a probabilistic measure for seismic performance assessment of structural components or systems. There are two different end products of seismic fragility analysis: damage probability matrix and fragility curve.

Damage probability matrix (DPM) is a table that provides discrete values of damage state probabilities for specified levels of ground motion intensities. Each column of DPM stands for a constant level of ground motion intensity whereas each row of DPM denotes the probability of being in a predefined damage state. Hence, any element of DPM represents the probability of

experiencing a certain damage state for a specific level of ground motion intensity.

Fragility curves are continuous functions that represent the probability of exceeding predefined limit (or performance) states for specific levels of ground motion intensity. Fragility curves can be developed for structural and nonstructural components, or they can be generated for structural systems and assemblies. In the field of earthquake engineering, the most common application is to generate fragility curves for building structures. Depending on the characteristics of the building stock in the region of interest, the fragility curves can be derived for many different structural types (i.e., steel, reinforced concrete, or masonry buildings; low-, mid-, or high-rise construction; frame, wall, or mixed structures; etc.). Other than building structures, fragility curves have also been generated for infrastructures (like bridges, dams), lifeline systems (like transportation, power, water supply networks), unrestrained equipment, etc.

Fragility curves can be used for different purposes. The main purpose is to determine the seismic performance of new or existing structural systems. In the former case, the fragility information is obtained for optimal design and in the latter case for condition assessment. Fragility curves can also be employed in order to assess the efficiency of different intervention techniques on existing structural systems. When the curves are derived to represent a certain class of structural systems, they can also be used for regional seismic damage and loss estimation studies. Such studies are very popular nowadays since they can be employed for pre-earthquake mitigation efforts and postearthquake decision-making processes.

There is a close relationship between fragility curves and DPMs so that the information obtained from fragility curves can be converted to construct DPMs or vice versa. Figure 1 demonstrates how to generate DPM from a given set of fragility curves. The vertical axis, simply named as “probability,” actually stands for the probability of exceeding a limit state. The horizontal axis represents the complete range of ground motion intensity levels (ILs). Different

ground motion intensity parameters can be used in the generation of fragility curves. As seen from the figure, four limit states (LSs) have been assigned, which in turn means that there exist five damage states (DSs). Attainment of limit states is an important phase of fragility curve generation and is discussed in following sections. The columns of DPM are obtained by intersecting the fragility curve set with vertical lines (dashed lines in Fig. 1) at specific intensity levels and calculating the damage state probabilities, which are corresponding portions between any two limit states in these vertical alignments.

Different Approaches for Seismic Fragility

There are four main resources to generate the seismic fragility of a structural system or component: expert opinion, field data, experimental data, and analytical simulations.

One of these main data sources for the derivation of fragility curves is based on the opinion of the experts from the field of earthquake engineering that are invited to make a prediction about the probable damage state of a structure or a class of structures under different levels of seismic action. The fragility curves generated by this judgment-based data are called as “judgmental fragility curves.” Until recently, expert opinion was the main source to generate fragility information especially for a wide range of structures and performance limits in the United States by the introduction of the ATC-13 document (Applied Technology Council 1985) and HAZUS earthquake loss estimation methodology (National Institute of Building Sciences 1999). However, the main issue that impairs the use of expert opinion is the subjectivity and bias of the collected data since it depends on the unique experience of the experts involved and it is very difficult to quantify this subjectivity or eliminate the bias.

Fragility curves can also be derived by using the structural damage data obtained from field observations after earthquakes. The fragility curves obtained by this approach are called as

Seismic Fragility Analysis, Fig. 1 Conversion from a set of fragility curves to DPM (Prepared by using the data from Erberik and Elnashai 2004)

“empirical fragility curves.” Although it is difficult to construct empirical fragility curves from field observations, the obtained fragility curves are invaluable in the sense that they reflect the exact behavior of a structure or a class of structures. The difficulty comes from the fact that for empirical fragility curve generation, an extensive field data from many earthquakes with different magnitudes should be gathered. For instance, Rossetto and Elnashai (2003) gathered a huge database that is composed of 340,000 buildings inspected after 19 different earthquakes and locations in order to construct the empirical fragility curves for European-type reinforced concrete frame buildings. Furthermore, it is not an easy task to estimate the spatial distribution of earthquake intensity at different locations where the buildings under consideration reside. Another

issue is the nonuniformity of field data in terms of ground motion intensities and damage state definitions since it is being collected from many different resources. In this case, it becomes crucial to convert all field data to a standard format in order to use in the generation of empirical fragility curves.

Experimental data can be employed in the generation of fragility curves by using a similar approach as in the case of empirical fragility curve generation based on field data. However, in order to obtain sufficient data for fragility curve generation, it may be required to conduct a large number of laboratory tests with different levels of loading intensities and material properties. Hence, this way of generating fragility curves is generally an expensive solution and therefore not popular when compared to the

generation of fragility curves based on analytical simulations.

The most commonly used data source for quantification of seismic fragility comes from the analytical simulations since most of the issues encountered in the case of judgmental, empirical, and experimental-based approaches are handled by the use of numerical data obtained through analytical modeling. It is possible to generate response statistics for any type of structure or class of structures subjected to a wide range of ground motion intensities. However, in this case, there are two main issues: computational effort and limitations in analytical modeling due to idealization of actual structures. Although the computing technology is very powerful nowadays, generation of analytical fragility curves can take considerable time and effort depending on the level of detail in analytical modeling. In some cases, it can even become unfeasible such as when it is required to run a dynamic analysis thousands of times on a detailed finite element model of a special structure. Hence, this means that it is inevitable to introduce some simplifications and idealizations to the analytical model. But then, the issues arising from limitations of analytical modeling begin to play an important role in seismic fragility analysis. This may cause the deviation of the response of the analytical model from the actual behavior of the structure under concern. As a result, analytical approach to quantify seismic fragility always possesses a trade-off between accuracy and computational effort. In this regard, there are different alternatives to be used as the analysis method for seismic fragility analysis. These can be listed as linear static, linear dynamic, nonlinear static, and nonlinear dynamic methods from the simplest to the most complex approach. Among these, linear static method is not generally used in seismic fragility analysis due to the dynamic nature of the actual response. However, nonlinear static analysis is an alternative when it is difficult to carry out series of dynamic analyses to generate fragility functions. Linear dynamic analysis can sometimes be used, especially when the structural system under concern exhibits brittle behavior under seismic action and does not go far

beyond the elastic range of response, like unreinforced masonry structures. The best method is always nonlinear dynamic approach, but in practice, this may not be the case due to computational difficulties as discussed above.

Components of Seismic Fragility Analysis

Basically, seismic fragility analysis is the comparison of seismic capacity and demand and to estimate whether the seismic capacity is exceeded for a well-defined performance level when the structural system is subjected to specified levels of ground motion intensity. Due to the probabilistic nature of seismic fragility analysis, both seismic capacity and demand are defined by probability functions in terms of certain random variables to quantify all the uncertainties involved in the process.

In the field of earthquake engineering, there is no consensus on the best method for seismic fragility analysis. However, the general framework of seismic fragility analysis can be more or less presented as shown in Fig. 2. Each element of the flowchart defines a different component of seismic fragility analysis procedure. The elements enclosed by boxes with dashed lines can be regarded as a single component in the analysis. Each component of seismic fragility analysis is explained in detail in the following paragraphs.

The first component is the development of the analytical model and generation of structural simulations to account for structural variability. At this stage, the major challenge is the selection of the analytical model. Depending on the level of idealization and simplification, a wide range of models from equivalent single-degree-of-freedom (SDOF) systems to detailed finite element (FE) meshes can be employed in order to carry out the structural simulations (Fig. 3). Since a huge number of analyses are required to construct the response statistics and the fragility curves, the use of a simple model (like a SDOF model) becomes very advantageous in terms of computational effort. However, it should be noted that such a simple model can only realize

Seismic Fragility Analysis, Fig. 2 General framework of seismic fragility analysis

Seismic Fragility Analysis, Fig. 3 Different levels of idealization for analytical modeling of structural systems from the simplest to the most sophisticated

the global behavior of the structural system to some extent and it is blind to local structural characteristics or construction details. Hence, such models are generally used to generate the fragility curves of a class of structures (for instance, mid-rise reinforced concrete frame structures) in order to predict regional damage or loss. On the other hand, it is not possible to use simplified models for special structures, in which the structural and construction details are important and should be reflected in the seismic fragility analysis. A good example for this case is historical masonry structures, which are unique and possess their own structural characteristics. In such cases, finite element mesh modeling seems to be the best solution, but then the problem is to carry out numerous analyses (especially

if they are dynamic in nature) on this finite element mesh within a reasonable period of time. Briefly, the problem of selecting the appropriate modeling strategy is multidimensional, and one has to make the decision by considering all the pros and cons.

After the selection of the analytical model, the next step is to generate the structural simulations. Due to the probabilistic nature of seismic fragility analysis, some of the major structural parameters within the analytical model are considered as random variables with appropriate probability density functions assigned to them. Normal or lognormal distributions are commonly used for convenience. These can be mechanical properties like stiffness or strength to account for the material variability or geometric properties like

length, height, or cross-sectional dimensions. In order to generate the population of analytical simulations, a sampling method is required. The most popular method is Monte Carlo sampling (Metropolis and Ulam 1949). It is a robust and a straightforward method to generate structural simulations, but the disadvantage is that it requires a very large sample size, which makes the method unfeasible to use in the case of detailed and complex analytical models. This shortcoming opens a door to constrained sampling methods to reduce the sample size, like the Latin hypercube model (McKay et al. 1979).

Since dynamic analysis is an indispensable tool for seismic fragility analysis, characterization of ground motion intensity becomes an important component to generate fragility information. To conduct dynamic analyses, there are two options: to employ (1) actual or (2) synthetic ground motion records. If it is possible to find a sufficiently large number of records from different earthquakes in the region of interest, then the first option seems to be the best solution to reflect the effect of regional seismicity and local geologic characteristics. Ground motion records are generally selected to cover the whole range of intensity levels. However, this may induce the need to scale ground motion records to fill the gaps of seismic intensity levels, especially for high intensities. Scaling ground motion records is a different research topic in earthquake engineering, and there are many different methods that one can employ. The second option, using synthetic ground motion records, becomes crucial if there exists an insufficient number of actual ground motion records in the study region. Generating synthetic ground motion records is another huge area of research in earthquake engineering, and there are many different approaches in the literature. However, it should be noted that in order to generate reliable synthetic ground motion records in a region, geologic and seismological parameters should be well studied and known beforehand.

Another challenge in seismic fragility analysis is the selection of the ground motion intensity parameter since it is difficult to determine a unique parameter that fully characterizes

earthquake ground motions. Descriptive parameters like Modified Mercalli Intensity (MMI) had been used in the past, but they are no more popular due to the fact that they are judgmental and subjective measures. In addition, they do not correlate well with damage. The most commonly used group of parameters are single-valued (or peak-valued) parameters like peak ground acceleration (PGA) and peak ground velocity (PGV). These parameters can be easily obtained from the ground motion time history. However, single-valued parameters are insensitive to frequency content and duration of the ground motion record, which is extremely important for obtaining the seismic performance of a structural system in some cases. To overcome the shortcomings of single-valued parameters, spectral parameters like spectral acceleration (S_a) and spectral displacement (S_d) can also be employed since these are enhanced parameters which are functions of both the ground motion characteristics and SDOF system properties. Although rare, there are also cases where involved parameters like effective peak acceleration, Housner's spectral intensity, and input energy have been used as the intensity parameter in seismic fragility analysis.

After generating the structural simulations and selecting the ground motion records, the next step is to carry out a large number of analyses in order to build up the response statistics. These are scattered plots in which the vertical axis stands for a response parameter like displacement, drift, or force, whereas the horizontal axis represents the ground motion intensity parameter (see Fig. 4a). All the uncertainty and the variability arising from the ground motion characterization and the analytical simulation is reflected in this plot. Although scattered, the general trend in this plot is that as the ground motion intensity increases, seismic demand characterized by the response parameter also increases.

The response statistics can be employed to generate fragility curves if some limit states are defined as a function of the response parameter under consideration. This is another important stage in seismic fragility analysis because the definition of a limit state directly affects the

Seismic Fragility Analysis, Fig. 4 Schematic representation of the fragility curve generation procedure (Adopted from Ugurhan et al. 2011) (a) response statistics, (b) probability of exceeding a limit state at a

specific ground motion intensity, (c) discrete fragility information for a certain limit state, (d) continuous fragility function

corresponding fragility curve. There are many different ways to attain the limit states. Limit state values can be directly obtained from the previous studies in the literature if the structural type under consideration had been studied before. However, in most of the cases, the local and special characteristics of the structural system requires the attainment of new limit states. In this case, the best method is to rely on field observations or experimental findings if any. In the absence of such data, analytical approaches can be used to determine the limit states. For instance, nonlinear static analysis, in particular pushover method, is a good candidate for this task. The instantaneous capacity of the structural system and the progression of damage can be monitored in this type of analysis.

Generally, two or more limit states are defined in seismic fragility analysis. For instance, in

FEMA-273 document (Federal Emergency Management Agency 1997), three limit states were defined as “Immediate Occupancy,” “Life Safety,” and “Collapse Prevention” in terms of interstory drift. The limit states are generally considered as deterministic parameters. However, there are cases in literature in which limit states are also considered in a probabilistic manner to account for the variability in seismic capacity.

Each vertical line of scattered data in response statistics stands for a specific ground motion intensity level with its own statistical distribution. If the limit states are also added to the same plot, then it becomes possible to determine the probabilities of exceeding the limit states at specific ground motion intensity levels. This is illustrated in Fig. 4b, in which LS_i represents the i^{th} limit state and GMI_j represents the j^{th} intensity

level. Hence, the shaded area in the given distribution denotes the probability of exceeding the i^{th} limit state at the j^{th} ground motion intensity level, i.e., $P[D \geq LS_i | GMI_j]$. The value obtained represents one of the data points in Fig. 4c. If this process is repeated for different intensity levels for the whole range, the discrete fragility information shown in Fig. 4c can be obtained for a certain limit state. Then, repeating the process for different limit states reveals a set of fragility information. The last step is to convert this discrete information into a continuous function by curve fitting. The continuous fragility functions are generally represented by cumulative lognormal distribution (Fig. 4d), although other forms of equations (like exponential function) have also been used in the literature. The shape of the fragility curve is dependent on the overall uncertainties involved in the generation process. Less variability means a steeper fragility curve. In the limit, the fragility curve with no uncertainty (i.e., deterministic case) turns out to be a step function.

Additional Information on Seismic Fragility Analysis

The topic of seismic fragility analysis has been a very popular and active research area in the field of earthquake engineering for the last two decades. Hence, there are many additional issues to be discussed related to this topic. Some of these are mentioned in the following subsections.

Different Analysis Approaches in the Literature

In the previous section, a fragility curve generation procedure that makes use of time history analyses was introduced. However, it should be stated that this is not the only alternative to generate fragility curves. For instance, instead of using time history analysis, incremental dynamic analysis (IDA) can also be used for the generation of fragility curves. In this approach, the structural system under consideration is subjected to a series of nonlinear time history analyses, in which the intensity of the ground motion is

increased until collapse at each run by using scaling methods (Vamvatsikos and Cornell 2002). Hence, it becomes possible to monitor the complete system response under seismic action from linear elastic behavior to collapse by using IDA approach, which makes it a good candidate for seismic fragility analysis.

In literature, there are two different nonlinear static procedures that have replaced dynamic analyses in the generation of fragility curves, named as capacity spectrum method (CSM) and displacement coefficient method (DCM). The CSM was first developed by Freeman et al. (1975) and then became more publicized thanks to the introduced in the ATC-40 document (Applied Technology Council 1996). It has been very popular since then in performance based earthquake engineering. The CSM method is based on the idea to compare a nonlinear capacity curve (obtained from a pushover analysis) in acceleration-displacement response spectrum (ADRS) format with an elastic demand spectrum that is reduced to account for equivalent damping. The intersection point is obtained by trial and error and it is called as “performance point”. The second method, DCM, was first introduced by the FEMA-273 document (Federal Emergency Management Agency 1997). Just like the CSM, it is based on constructing the pushover curve of the structural system under concern. Then, this information is converted into equivalent SDOF response. The final step is to modify the linear elastic response of this equivalent SDOF system by the help of some empirical coefficients that account for MDOF response, inelastic behavior, degradation, and P- Δ effect. The final product is an estimate of the maximum displacement of the structural system, called as “the target displacement.” By using both methods, it is much easier to generate fragility curves since it is only a matter of repeating the pushover analysis rather than carrying out complicated nonlinear time history analyses.

There is also a different class of analysis methods, called as response surface methods, which are employed to reduce the large number of computations in seismic fragility analysis. In these methods, a response function is generated

in terms of the major random variables (ground motion intensity parameter, geometric or mechanical properties) to predict the seismic response of structural systems without the need to carry out complex dynamic analyses. The other advantage of these methods comes from the fact that both seismic demand and capacity can be directly incorporated with their inherent joint probability distributions in the response surface, which can only be achieved by making qualitative physical assumptions in the other analysis approaches.

Quantification of Uncertainty in Seismic Fragility Analysis

Seismic fragility analysis requires the treatment of uncertainties involved in the process since both seismic demand and capacity possess different sources of uncertainty. The uncertainties may either arise from inherent randomness in nature (aleatoric uncertainty), which cannot be reduced, or from lack of knowledge or data (epistemic uncertainty). From another point of view, the uncertainties in seismic fragility analysis may belong to ground motion characteristics and the demand on the structural system or the structural capacity under seismic action, performance level identification, and the limitations in analytical modeling. All sources of uncertainty should be quantified and reduced (if possible) in the generation of fragility curves.

Most of the researchers have stated that the uncertainties arising from ground motion characteristics outweigh the uncertainties due to structural system characteristics and analytical modeling. But, of course, this may not be always the case, depending on the specific properties of seismic action and the structural system under concern.

The reliability of the generated fragility curves can be tested by plotting the confidence intervals for selected levels of confidence with upper and lower bounds. If the uncertainties arising from the components of seismic fragility analysis are significant, the confidence intervals will eventually be large, indicating a poor estimate of performance that is represented by the fragility information.

Combined Fragility Curves

Fragility curves for individual structures can be combined together to yield the fragility information of a class of structures with similar properties. This is especially required for regional damage and loss estimation, to obtain the fragilities of different construction types such as reinforced concrete frame structures, unreinforced masonry structures, etc. In this case, the combined fragility curve can be obtained by using (Shinozuka et al. 2000)

$$F_C(X) = \sum_{i=1}^M P_i F_i(X) \quad (1)$$

where

$$P_i = \frac{N_i}{\sum_{i=1}^M N_i} \quad (2)$$

In these equations, F_C stands for the combined fragility, whereas F_i represents the fragility curve of the i^{th} individual structure and X denotes any ground motion intensity parameter used in the generation of the fragility curve. Parameter N_i is the number of structures that the fragility information F_i belongs to, and the summation in the denominator of Eq. 2 represents the total number of structures in that specific class for which the information will be combined.

Fragility Surfaces

In some cases, it becomes difficult to obtain the seismic fragility of a structural system by using a single ground motion intensity parameter since there is no such unique parameter that is perfectly correlated with seismic damage as mentioned above. Then, it is possible to use two different ground motion intensity parameters together in the development of fragility information, which is called as fragility surface rather than fragility curve. In this case, there are two horizontal axes that define the ground motion intensity and one vertical axis that defines the probability of exceeding a certain limit state. This means the response statistics obtained can be plotted as a surface, not a curve. The dual ground motion intensity parameters for fragility surfaces can be

selected as magnitude and distance, PGA and PGV, spectral acceleration or displacement at two different vibration periods of the structural system (for instance, the first and the second vibration mode), etc.

Summary

Seismic fragility analysis can be regarded as a probabilistic measure for seismic performance assessment of structural components or systems. This analysis concept is very popular since it can be used in different research areas of earthquake engineering. Due to its probabilistic nature, it requires the use of random variables to characterize both seismic demand and capacity. In addition to this, there exist challenges such as the idealization of structure through an analytical model, selection of the ground motion intensity parameters and the analysis approach, attainment of the limit states, and quantification of the involved uncertainties. That is why the researchers in this field have used many different approaches and methods to obtain their own seismic fragility information. But the main goal is always to predict the performance of structural systems with a quantified level of confidence under different levels of seismic action.

Introduction

The importance of infrastructure to both the fabric of society and its economy is becoming increasingly more apparent. The robustness of infrastructure systems can be judged by their capacity to accommodate change over time. However, the rapid rate at which our infrastructure is aging requires new solutions for providing a resilient infrastructure that can last for future generations.

Earthquakes are paramount among the natural hazards impacting the infrastructure. The past several decades have witnessed a series of costly and damaging earthquakes. The events would have even more devastating effects if a major earthquake were to hit an old and unprepared infrastructure. The challenge that engineers today face is not only on how to construct new infrastructure with proper resistance to earthquakes but rather to update older structures that do not have the proper defense should a natural disaster occur. Failing to modernize older infrastructure could result in very serious consequences.

Offshore platforms are one of the key infrastructure systems housing the facilities for exploration and production of oil and gas. In addition to acting as accommodation for offshore workers, these platforms contain a range of equipment from power generation to oil processing. Assessing the reliability of these structural systems is highly complicated due to the complexity of interaction between various elements. It is possible to classify the offshore platforms further as floating and fixed offshore platforms (Sadeghi 2007), with usage depending on the depth of water at the installation location. These structures are popular in the waters of California, the Gulf of Mexico, Nigeria, the North Sea, and the Persian Gulf.

This entry will focus on a very specific and popular type of offshore platform, the fixed steel jacket platform (FSJ). According to Ferreira (2003), there are around 7,500 FSJ platforms distributed around the world. These platforms have been popular because of their relatively simple design and the availability of oil at shallow waters in the initial days of exploration.

However, as the resources in shallow water have started to extinguish, the exploration activities have moved to deeper waters. Nonetheless, there are many fixed steel jacket platforms that are still in service.

When the FSJ platforms were originally designed, the design life was considered as 25 years. However, due to the continued availability of hydrocarbons at some locations, the operators are looking at various options to extend the design life. For example, in the United Kingdom Continental Shelf (UKCS) sector of the North Sea, out of the 288 offshore installations, about 50 % of the fixed platforms have exceeded their design life (Stacey et al. 2008). When it comes to extending the life of these structures, there are various key limit states one needs to consider, depending on the geographical location. For example, the effects of wave fatigue on offshore structures are a key consideration in one zone, whereas the structural response under earthquakes is a serious limit state at a different location.

Considering the complexity and popularity of these structures, this entry looks at ways to characterize the probabilistic response of FSJ platforms under earthquake loads. The seismic vulnerability curve or seismic fragility curve is one of the most important elements in the assessment of seismic damage and the evaluation of the performance of different structural systems. The fragility curves are used to represent the probabilities of structural damage due to earthquakes as a function of ground motion indices such as peak ground acceleration (PGA), spectral acceleration (S_a), and spectral displacement (S_d). The characterization of earthquake excitation and the identification of different damage levels have an important role in developing the fragility curves and understanding the seismic performance of these structures.

This entry provides details of the development of fragility curve for a typical FSJ offshore platform using the SAC-FEMA technique. The following sections provide mathematical details of the SAC-FEMA technique, an overview on the reference structure and establishment of dynamic characteristics. Then, the ground motions used in

fragility analysis and the analysis results are discussed. The entry concludes with suggestions to formulate a better inspection and maintenance framework based on the summary of findings.

Seismic Fragility Analysis of Structures

Theory of Fragility Analysis

Introduction

Seismic damage and loss estimations are essential for disaster planning and formulating damage-reduction and insurance policies. Regional loss estimation can be mathematically described through Eq. 1, as shown below (Kwon 2007):

$$P[Loss] = \sum_s \sum_{LS} \sum_d P[Loss | D = d] \cdot P[D = d | LS] \cdot P[LS | IM = s] \cdot P[IM = s] \quad (1)$$

where $P[\bullet]$ = probability of events in the brackets. The term *Loss* refers to direct or indirect losses from a seismic event; *IM* is an intensity measure of a seismic hazard such as spectral acceleration or peak ground acceleration (PGA); and *s* is a realization of the intensity measure. $P[LS | IM = s]$ is a conditional probability of attaining structural limit state (LS), and $P[D = d | LS]$ is a conditional probability of attaining damage (minor, moderate, or major), which is a qualitative measure. The loss of a region is determined based on the damage state. Among these elements, the term, $P[LS | IM = s]$, refers to strong, motion-shaking severity influencing the probability of reaching or exceeding a specified performance limit state. This term is referred as *vulnerability* or *fragility*. The strong, motion-shaking severity may be expressed as an intensity, peak ground parameters (PGA, PGV, or PGD), or spectral ordinates (S_a , S_v , or S_d) corresponding to a fundamental structural period.

Analysis Techniques

Among others, some practical approaches to perform fragility analysis are the SAC/FEMA

method, effective fragility analysis method, and methods based on response surface (Pinto et al. 2004). The SAC-FEMA method, which provides the basis for the FEMA-350 (2000) for the seismic design and assessment of steel moment-resisting frames, is the most practical approach among these options. The SAC-FEMA method is efficient when the response is predominantly dominated by the first mode and when failure is influenced by a single scalar variable, for instance, the interstory drift. However, when failure involves several random variables, then one would need to use methods based on effective fragility analysis techniques or response surfaces.

Mathematical Details of SAC-FEMA Technique

The SAC-FEMA method (Pinto et al. 2004) is one of the popular methods to perform vulnerability analysis. In the SAC-FEMA approach, the seismic hazard $P[IM = s]$ is defined in terms of spectral acceleration ordinates, calculated at the fundamental period of the structure. In this method the failure occurs when the maximum demand over the duration of the seismic excitation exceeds the corresponding capacity. The seismic hazard is combined with the drift demand to define drift hazard as follows:

$$H_D(d) = \int P[D \geq d | S_a = x] | dH(x) | \quad (2)$$

where $|dH(x)|$ means the absolute value of the derivative of the site's spectral acceleration hazard curve times dx . The seismic demand is related to the hazard as follows:

$$\hat{D} = a S_a^b \quad (3)$$

where $\hat{D}$ is the median value of demand *D*. The constants, *a* and *b*, are determined from a regression analysis of structural demands calculated from the dynamic analyses. The term β_D , standard deviation of the natural logarithm of demand *D*, is calculated about the median value of demand *D*. Ideally, at each spectral acceleration value, there would be multiple demand values, as two ground motions with same spectral acceleration could result in different drifts. Hence, the

median value over each set of demands is corresponding to a spectral ordinate value that needs to be calculated. Also every set is associated with a unique dispersion. To account for the dispersion, a random variable ϵ , with unit median and dispersion equal to β_D , is introduced. Equation 4 then updates to:

$$D = aS_a^b \epsilon \quad (4)$$

However, for simplicity, only one demand is used for a given spectral acceleration, and it is assumed that this value would be the median demand value, and the dispersion is assumed to be the same across all the spectral acceleration values. The demand D is assumed to be log-normally distributed about the median, with standard deviation of the natural logarithm equal to β_D . For a given intensity level, the probability of reaching a structural demand, d , can be calculated using cumulative distribution function of log-normal distribution, given as:

$$P[d \leq D | S_a = x] = 1 - \Phi\left(\frac{\ln(d/ax^b)}{\beta_{D|S_a}}\right) \quad (5)$$

Equations 4 and 5 result in a closed form solution of drift hazard as shown below:

$$H_D(d) = P[D \geq d] = H(S_a^d) \exp\left[\frac{1}{2} \frac{k^2}{b^2} \beta_{D|S_a}^2\right] \quad (6)$$

The drift hazard should be combined with the drift capacity, C , to evaluate the annual probability of the performance level not being met, P_{PL} .

$$P_{PL} = \int P[C \leq d] |dH_D(d)| \quad (7)$$

The drift capacity C is assumed to follow log-normal distribution with a median value of $\hat{C}$ and dispersion β_C . Therefore, the probability of the capacity, C , being lower than the demand, d , is expressed as

$$P[C \leq d] = \Phi\left(\frac{\ln(d/\hat{C})}{\beta_C}\right) \quad (8)$$

Substituting Eqs. 6 and 8 into 7, the probability of annual failure is given as

$$P_{PL} = H\left(s_a^{\hat{C}}\right) \exp\left[\frac{1}{2} \frac{k^2}{b^2} \left(\beta_{D|S_a}^2 + \beta_C^2\right)\right] \quad (9)$$

Previous studies have shown that P_{PL} is dictated by the hazard and not by the uncertainties in the demand and capacity. The above procedure, summarized in Eq. 9, fully couples hazard, demand, and capacity. However, as highlighted in Kwon (2007), the derivation of vulnerability curves is more advantageous than calculating fully coupled risks.

Application to a Typical Fixed Steel Jacket Platform

Analytical Modeling

Fragility analysis was performed on a typical FSJ offshore platform that was designed according to the API guidelines and presented by Nordal et al. (1987). It is assumed that all the lateral forces are transferred to the foundation mainly by the diagonal braces. Furthermore, at each level, the horizontal X-braces transfer the forces among the four vertical frames. In this study, the performance of the platform is estimated through fragility analysis when subjected to seismic forces. A 2-D model of the X-braced vertical frame on grid line A is developed in ETABS (2008); the section sizes are available in Nordal et al. (1987). A screenshot of this analytical model is shown in Fig. 1.

The numerical model of the structure is developed based on the following assumptions:

- All the connections are assumed to be pinned connections.
- All the members are modeled as truss elements.
- Rigid diaphragm condition is assumed only for the level 4, where the mass is defined.
- All supports are assigned pin conditions.

Seismic Fragility of Aging Offshore Platforms,

Fig. 1 Analytical model in ETABS (a) 3D view (b) elevation

- The primary lateral force-resisting members are the braces.
- Nonlinearity effects are not modeled.

Based on the work of Stear and Bea (1997), the total deck load being supported is taken as 51 MN, which would be shared by the four frames in the y -direction. Hence, a mass of 12.75 MN (12,750 kN) is assigned to the top node of the frame. In addition, as discussed in the modeling assumptions, rigid diaphragm condition (all the nodes in a given floor are constrained together) is assigned for the top level.

Evaluation of Dynamic Properties

Using the above defined mass and section sizes, a modal analysis is performed to obtain the fundamental period. First two mode shapes of this structure along with their corresponding periods are shown in Fig. 2. The fundamental period was also determined using static pushover analysis to verify the period obtained using the modal analysis. The fundamental period obtained using both the analyses are in good agreement.

Selection of Ground Motions

For demonstrative purposes, ground motions are selected from the Pacific Earthquake Engineering

Seismic Fragility of Aging Offshore Platforms, Fig. 2 Mode shapes of the frame (a) Mode 1 ($T = 3.71$ s) (b) Mode 2 ($T = 0.123$ s)

Center (PEER) New Generation Attenuation (NGA) database. However, it is recommended to select the ground motions based on the site location, if available. The database is composed of 3,551 ground motion recordings that represent over 160 seismic events (including aftershock events) ranging in magnitude from M4.2 to M7.9 (Chiou et al. 2008). A total of 30 far-field ground motions are selected from the PEER NGA database. The PGA range for the final selected suite of ground motions, listed in Table 1, is 0.2 g to 1.8 g with an average of 0.5 g. The ground motion suite includes earthquakes that occurred from 1971 to 1999. The spectral acceleration at the fundamental period of the structure, 3.71 s corresponding to 5 % damping, is obtained by constructing the elastic response spectra of each ground motion (Seismosoft 2011). For instance, for the first ground motion in Table 1, Loma Prieta earthquake (A01090), the pseudo-acceleration elastic spectra is shown in Fig. 3.

Calculation of Story Drift

For a linear elastic system, the peak story drift can be obtained from the elastic pseudo-spectral

acceleration using the following equation (Chopra 2010):

$$A = \omega_n^2 D = \left(\frac{2\pi}{T_n} \right)^2 D \quad (10)$$

where ω_n is the natural frequency of the structure, D is the peak deformation of the structure due to earthquake, T_n is the natural period of the structure, and A is the pseudo-spectral acceleration corresponding to T_n . The peak displacement of the top node, obtained above, is divided with total story height to obtain the peak drifts. The graph of peak drift versus spectral acceleration is shown in Fig. 4 for the ground motions listed above.

In general, the pseudo-spectral acceleration is very low because of the higher fundamental period. When compared to buildings, the percentage increment in the mass must be higher than the percentage increment in stiffness for the offshore structures. Having obtained the seismic hazard expressed in spectral acceleration and the demand expressed in interstory drift, a reliability analysis can now be performed. The limit states are discussed in the following section.

Formulation of Limit States

The performance limit states are of prime importance in the fragility analysis and need to be carefully determined. The three performance levels that were used for the offshore steel-braced frame are given in Table 2. However, more investigation is required to ascertain the applicability of these limit states to offshore structures. The limits corresponding to each level are also given in Table 2.

Fragility Analysis Results

Using the outlined procedure in section “[Mathematical Details of SAC-FEMA Technique](#),” the fragility curves are developed for the three limit states discussed in the previous section and are shown in Fig. 5. It can be inferred that the probability of reaching the higher limit state, characterized with drift 2 %, is almost 100 % for a seismic hazard as low as 1.2 g, which signifies the non-robust seismic design of the structure.

Seismic Fragility of Aging Offshore Platforms,

Fig. 3 Pseudo-acceleration elastic response spectra ($\zeta = 5\%$)

Seismic Fragility of Aging Offshore Platforms, Fig. 4 Peak drift versus spectral acceleration

Seismic Fragility of Aging Offshore Platforms, Table 2 Structural performance levels and damage, expressed in terms of drift (Source: ASCE 2007)

Elements	Type	Structural performance levels		
		Collapse prevention	Life safety	Immediate occupancy
Braced steel frames	Primary	Extensive yielding and buckling of braces Many braces and their connections may fail	Many braces yield or buckle but do not totally fail Many connections may fail	Minor yielding or buckling of braces
	Secondary	Same as primary	Same as primary	Same as primary
	Drift	2 % transient or permanent	1.5 % transient 0.5 % permanent	0.5 % transient negligible permanent

The slope of the fragility curve decreases with the limit state which implies that relatively higher hazard increment is necessary to reach the probability of failure as the limit state is increased.

Summary

In this entry, the seismic performance of a typical fixed steel jacket platform is evaluated through fragility analysis. The analysis has shown that the considered offshore platform cannot withstand even the seismic hazard corresponding to the collapse prevention performance level. This undermines the robustness of such structures which are aging, for the ever-increasing seismic hazard. Even though the results were shown on a simple elastic system, the authors believe that the implications could be more serious when an inelastic system was used, as the drift demand would be much higher albeit with a reduction in

force demand. Though the fragility curves are derived where the demand is expressed in terms of interstory drift, similar curves can be derived when the demand is expressed in terms of acceleration, residual drift, etc.

The procedure described herein to perform fragility analysis is simple and practical. Hence, when assessing the performance of similar FSJ platforms, practicing engineers can implement it easily. The above results may also be used to prioritize the retrofiting strategy of aging platforms. Fragility curves provide a quick, yet, sufficient insight in to the performance robustness of the structures and help to determine the members that need the utmost attention. This is also ideal for planning the inspection and maintenance strategies for these structures. It is to be noted that other significant limit states also influence such decisions for FSJ platforms; the presented approach is recommended for characterizing the seismic effects along with appropriate consideration of other limit states.

Recording seismic signals, whether in digital or analog form, gives a number in a computer or an amplitude on paper (Fig. 1). For velocity sensors this number is proportional to ground velocity above a certain frequency, and for accelerometers the number is proportional to ground acceleration.

What is really needed is the true motion of the ground in displacement, velocity, or acceleration. So considering Fig. 1, the signal to the right is recorded, and the signal to the left is what is needed. They are obviously different. Seismologists most often use displacement while engineers prefer acceleration. In most cases the correction is not as easy as just multiplying with a constant to get the ground motion for two reasons:

- The seismic sensor is not recording the desired ground motion magnitude: displacement, velocity, or acceleration and a transformation must be done.
- The response of the seismic sensor to the ground motion, as well as the response of the recorder, is in general frequency dependent, so a frequency-dependent correction must be made (Fig. 1).

It is thus essential to know how the seismic sensor and recorder modify the input signal, the ground motion, to produce the recorded output signal. If, e.g., for given harmonic ground

amplitude displacement $X(\omega)$, the output amplitude $Y(\omega)$ can be calculated as

$$Y(\omega) = X(\omega) \cdot A(\omega) \quad (1)$$

where $A(\omega)$ is the displacement amplitude response, then the displacement, $X(\omega)$, of the ground can simply be calculated as

$$X(\omega) = A(\omega)/Y(\omega) \quad (2)$$

$A(\omega)$ has traditionally been called the magnification, since for an analog recorder $A(\omega)$ gives how many times the signal is magnified at different frequencies.

In this document, a description of the response function for different kinds of sensors will be described, as well as methods used for making a correction for the instrument response to arrive at the true ground motion, whether in time domain or frequency domain.

The Elements of a Seismic Station

A seismic station consists of a sensor connected to a recorder. The sensor has an output in volts proportional to the ground velocity (velocity sensor) or to the ground acceleration (an accelerometer), and this output is generally only constant in a specific frequency range. The proportionality constant is called the generator constant G and has units of $V/(m \cdot s^{-1})$ and V/g (g is the gravity acceleration) for the two types of sensors, respectively. The sensor output signal enters the digital recorder which will have some filter built in at high frequency to avoid aliasing. The digitizer will give out a number (called counts) proportional to the input voltage, and this defines the digitizer sensitivity in terms of counts/V.

Frequency Response of a Linear System

A seismic sensor and associated electronics in the seismic recorder is assumed to behave as a linear

Seismic Instrument Response, Correction for, Fig. 1 The input is the ground moving with a maximum displacement 0.02 mm. This “signal” goes through an

accelerometer and becomes a new signal with a maximum number (count) of 1,250,000. Note also that the frequency content is different for input and output

system. The linearity means that there is a linear relationship between input signal and output signal. If the input signal is $x(t)$ and the output $y(t)$, then multiplying $x(t)$ with a constant will result in an output signal multiplied with the same constant. For example, if the ground velocity is doubled, then the output from the seismometer is also doubled. If two signals of different frequency and amplitude are input, then also two signals with the same frequencies (with different amplitude and phase) are output. The frequency-dependent relation between the output and the input is called the frequency response function. For a more complete description, see Scherbaum (2007).

A very simple linear system is the RC filter consisting of a resistor R and a capacitor C . An RC low-pass filter is seen in Fig. 2.

This circuit lets low frequencies pass without attenuation, while high frequencies are attenuated due to the frequency-dependent impedance of the capacitor. For a sine wave signal of frequency f , the capacitor impedance is the relation between the voltage amplitude at the capacitor terminals and the amplitude of the current flowing through the capacitor.

The impedance Z_c of a capacitor seen by the input for a sine wave signal of frequency f is

$$Z_c = \frac{1}{2\pi fC} = \frac{1}{\omega C} \quad (3)$$

where C is the capacitance (F) and $\omega = 2\pi f$. The voltage over the capacitor is delayed by one fourth cycle (90°) with respect to the current through it. Considering that the RC filter is a frequency-dependent voltage divider, using a monochromatic signal of angular frequency ω and amplitude $X(\omega)$, $x(t) = X(\omega)\cos(\omega t)$, the

Seismic Instrument Response, Correction for, Fig. 2 RC low-pass filter. R is the resistor and C the capacitor. Input is $x(t)$ and output $y(t)$

output signal amplitude $Y(\omega)$ can be written as (e.g., Havskov and Alguacil 2010)

$$Y(\omega) = \frac{1}{\sqrt{1 + \omega^2 R^2 C^2}} X(\omega) = \frac{1}{\sqrt{1 + \omega^2 / \omega_0^2}} X(\omega) \quad (4)$$

where $\omega_0 = 1/RC$. ω_0 is also called the corner or cutoff frequency of the filter, and for $\omega = \omega_0$, the amplitude has been reduced to $1/\sqrt{2} = 0.707$ (see Fig. 4). From Eq. 4 the amplitude frequency response function of the filter $A(\omega)$ (since only amplitudes are considered) is

$$A(\omega) = \frac{1}{\sqrt{1 + \omega^2 / \omega_0^2}} = \frac{Y(\omega)}{X(\omega)} \quad (5)$$

If $A(\omega)$ is completely known, then the amplitude of the harmonic input signal $X(\omega)$ can be calculated from the measured signal as

$$X(\omega) = Y(\omega) / A(\omega) \quad (6)$$

The amplitude response can be measured very simply as shown in Fig. 3. By varying the frequency, both input and output amplitudes can be

Seismic Instrument Response, Correction for, Fig. 3 Measuring the amplitude and phase response function of an RC filter. The signal from a signal generator

goes directly to channel 1 (Ch1, *top trace*) on the oscilloscope and to channel 2 (Ch2, *bottom trace*) through the filter so both input and output is measured

measured at different frequencies to produce the amplitude response function.

From Fig. 3, it is seen that the output signal not only has been changed in amplitude but also has been delayed a little relative to the input signal; in other words, there has been a phase shift; see definition below.

In this example, the phase shift is negative (see definition in Eq. 7). The complete frequency response of the filter therefore consists of both the amplitude response function and the phase response function $\Phi(\omega)$; see Fig. 4. Considering a general input harmonic waveform $x(\omega, t) = X(\omega) \cdot \cos(\omega t)$ at frequency ω , the output can be written as

$$y(\omega, t) = X(\omega) \cdot A(\omega) \cdot \cos(\omega t + \Phi(\omega)) \quad (7)$$

The phase shift is here defined as a quantity being added to the phase as seen above. Thus comparing Fig. 4 and Eq. 7, it is seen that the phase shift is negative. This is the most common way of defining the phase shift, but the opposite sign is sometimes seen, and it may then be called phase delay or phase lag. So it is very important to know which definition has been used.

Using Eq. 7 to correct the amplitude and phase of a single monochromatic signal in time domain is easy, but to make the correction for a whole signal with different frequencies is not simple.

This can be considerably simplified if the complex representation of harmonic signals is used. Instead of writing $\cos(\omega t)$, the real part of the exponential function can be used:

Seismic Instrument Response, Correction for, Fig. 4 Amplitude and phase response of an RC filter with a corner frequency of 1 Hz. The phase response (or phase shift) is given in degrees

$$e^{i\omega t} = \cos(\omega t) + i \sin(\omega t) \quad (8)$$

Equation 7 can now be written as

$$\begin{aligned} y(\omega, t) &= X(\omega)A(\omega)e^{i(\omega t + \Phi(\omega))} \\ &= X(\omega)A(\omega)e^{i\omega t}e^{i\Phi(\omega)} \end{aligned} \quad (9)$$

$y(\omega, t)$ is now a complex number of which the real part is the actual output. This can be further simplified considering that any complex number Z can be written as

$$Z = a + ib = \sqrt{a^2 + b^2}e^{i\Phi} = |Z|e^{i\Phi} \quad (10)$$

where $\Phi = \tan^{-1}(b/a)$ which also follows from Eq. 8. The complex frequency response $T(\omega)$ can then be defined as

$$T(\omega) = A(\omega)e^{i\Phi(\omega)} = |T(\omega)|e^{i\Phi(\omega)} \quad (11)$$

and Eq. 9 can be written as

$$y(\omega, t) = X(\omega)T(\omega)e^{i(\omega t)} \quad (12)$$

Now only one complex function, $T(\omega)$, that includes the phase shift can therefore completely describe the instrument frequency response. So far only monochromatic signals have been used and the corrections can easily be made with both the real and complex representations Eqs. 7 and 12, so it might be hard to see why the complex representation of the response function is needed. Later it is going to be shown how an observed seismogram is corrected, not only for one amplitude at a time, but actually for the whole signal (containing a range of frequencies), which is possible with digital data. Obviously this cannot be done with one amplitude at a time, but will have to be done with the amplitude and frequency content of the whole signal, in other words, making spectral analysis. It will hopefully then be clear why a complex representation is needed.

Frequency Response of Seismic Sensors

There are two important types of seismic sensors:

1. Velocity sensor (seismometer). This sensor has an output proportional to velocity in a limited frequency band; see Fig. 5. This is both the case for the traditional passive seismometers like geophones (for frequencies down to about 1 Hz) and modern broadband seismometers (down to frequencies of 0.003–0.03 Hz).
2. Accelerometer. This sensor usually has an output proportional to ground acceleration from 0 Hz (DC) to some cutoff frequency (see Fig. 6). In some cases there will also be a lower cutoff, e.g., at 0.1 Hz.

Velocity Sensor

The complex response function for a velocity sensor for displacement, velocity, and acceleration is the following (Havskov and Alguacil 2010).

Displacement

$$T_d(\omega) = \frac{Z(\omega)}{U(\omega)}G = \frac{i\omega^3 G}{\omega_0^2 - \omega^2 + i2\omega\omega_0 h} \quad (13)$$

Velocity

$$T_v(\omega) = \frac{\omega^2 G}{\omega_0^2 - \omega^2 + i2\omega\omega_0 h} \quad (14)$$

Acceleration

$$T_a(\omega) = \frac{-i\omega G}{\omega_0^2 - \omega^2 + i2\omega\omega_0 h} \quad (15)$$

where G is the generator constant, ω_0 is the natural frequency of the sensor (the frequency at which it will oscillate if no damping), and h is the damping coefficient (how the motion of the mass is damped; see Fig. 5). It is seen that the only difference between the respective three types of response curves is the factor $i\omega$.

For the velocity response, the amplitude and phase response are (Fig. 5)

$$A_v(\omega) = |T_v(\omega)| = \frac{G\omega^2}{\sqrt{(\omega_0^2 - \omega^2)^2 + 4h^2\omega^2\omega_0^2}} \quad (16)$$

$$\Phi_v(\omega) = a \tan \left(\frac{\text{Im}(T_v(\omega))}{\text{Re}(T_v(\omega))} \right) = a \tan \left(\frac{-2h\omega\omega_0}{\omega_0^2 - \omega^2} \right) \quad (17)$$

It is seen that as the damping decreases, the sensor response to velocity becomes constant for frequencies above the natural frequency. It is also seen that if there is little damping, the sensor will have a high gain at the natural frequency, so damping is usually set to 0.707.

Seismic Instrument Response, Correction for, Fig. 5

The amplitude and phase response functions for a velocity seismometer with a natural frequency of 1 Hz. Curves for various levels of damping h are shown. It is assumed that the generator constant is 1

Accelerometer

The acceleration response curve for an FBA accelerometer is (Havskov and Alguacil 2010)

$$T_a(\omega) = \frac{G/\omega_f^2}{\omega_f^2 - \omega^2 + i2\omega\omega_f h} \quad (18)$$

where ω_f is the effective natural (angular) frequency with feedback. The amplitude of this response has a flat value of G from DC up to

this frequency (usually above 50 Hz). The instrument correction is then very easy since it is assumed that the feedback natural frequency of the sensor is very high compared to the frequencies of interest so the response for acceleration is simply approximated by multiplying with the generator constant

$$T_a(\omega) = G \quad (19)$$

The velocity and displacement response is then:

Velocity

$$T_v(\omega) = G \cdot i\omega \quad (20)$$

Displacement

$$T_d(\omega) = -G \cdot \omega^2 \quad (21)$$

So for engineering purposes, where acceleration is needed, it is very easy to correct for the accelerometer response since it is just a question of multiplying with a constant, while seismologist wanting displacement must make the transformation (corresponding to integrating the signal twice).

In practice, many accelerograms, especially – but not only – those recorded with earlier accelerographs, are affected by offset or baseline shifts that may influence the estimation of characteristic parameters of strong ground motion (Boore 2001). The source of this long-period noise may be true ground motions (rotation, tilt, local deformation) or instrumental (mechanical nonlinearity, electronic effects) and is not yet fully understood (Akkar and Boore 2009). Prior to any integration to compute the ground velocity or displacement, the accelerogram should be corrected from these effects.

In many practical cases, this correction may consist simply in applying a high-pass filter with a suitable cutoff frequency, as it will be shown below. In some cases, a particular processing scheme adapted to an individual record is required. In fact, most accelerogram databases (e.g., Internet Site for European Strong-motion Data, www.isesd.hi.is) include a “processed” version of each accelerogram, which usually consists of baseline correction, band-pass filtering, and conversion to ground motion units.

It is interesting to note that whether a velocity sensor or an accelerometer is used, it is possible to calculate displacement, velocity, and acceleration from both types of sensors; however, as is shown later, in practice, this will be frequency limited due to noise in the system.

Complete Frequency Response

For passive sensors, the above equations represent exactly the seismometer response, and for many broadband sensors, this is also the case up to a particular frequency. A recording of a seismic signal also involves the seismic recorder which also has a frequency response. Modern recorders have little amplitude change or phase shift in the main frequency band used, so the frequency dependence of the recorder is often ignored. Some recorders might modify the signal enough for a correction to be made. In order to completely describe the response for active sensors and possibly also include the response of the recorder, a more general representation of the response function must be used. It turns out that $T(\omega)$ for all systems made from discrete mechanical or electrical components (masses, springs, coils, capacitors, resistors, semiconductors, etc.) can be represented exactly (e.g., Scherbaum 2007) by rational functions of $i\omega$:

$$T(\omega) = c \frac{(i\omega - z_1)(i\omega - z_2)(i\omega - z_3).....}{(i\omega - p_1)(i\omega - p_2)(i\omega - p_3).....} \quad (22)$$

where c is the combined normalization constant for nominator and denominator polynomials, z are the zeros (or roots) of the nominator polynomial, while the zeros of the denominator polynomial (poles) are p . Using Eq. 22 to represent $T(\omega)$ is the so-called poles and zeros representation, which has become the most standard way.

For example, for the seismometer response function for velocity, $T_v(\omega)$ can be written as

$$T_v(\omega) = \frac{-(i\omega - 0)(i\omega - 0)}{(i\omega - p_1)(i\omega - p_2)} \quad (23)$$

where

$$p_1 = -\omega_0 \left(h + \sqrt{h^2 - 1} \right) \quad (24)$$

$$p_2 = -\omega_0 \left(h - \sqrt{h^2 - 1} \right)$$

So in addition to the poles p_1 and p_2 , the seismometer response function has a double zero at $z = 0$ and the normalization constant is -1 . Note that since h usually is smaller than 1, the poles are usually complex. Complex poles always appear as conjugate pairs. For the displacement response, the equation is

$$T_d(\omega) = \frac{(i\omega - 0)(i\omega - 0)(i\omega - 0)}{(i\omega - p_1)(i\omega - p_2)} \quad (25)$$

and there is thus one more zero. For the standard accelerometer, the displacement response is simply $(i\omega)^2$ which corresponds to two zeros.

For active sensors, there might be more poles and zeros representing the filtering inherent in active sensors.

The frequency dependence of a recorder can equally be represented by poles and zeros, so it is

just a question of adding to the equation in the pole and zero representation.

In addition to the frequency-dependent elements, a complete seismograph or accelerograph also has the frequency-independent elements, the generator constant, and the digitizer gain which has to be multiplied with the normalization constant.

Example

A seismometer has a generator constant $G = 300 \text{ V/ms}^{-1}$ and the digitizer has a sensitivity of 100,000 counts/V. The velocity sensitivity of the seismograph in the passband (flat for velocity) is then $100,000 \text{ counts/V} \cdot 300 \text{ V/ms}^{-1} = 3 \cdot 10^7 \text{ counts/ms}^{-1}$. This number must then be multiplied with the normalization constant for the rest of the system which is the sensor and possibly some filters. For displacement, the amplitude displacement increases with frequency (Fig. 6), but that is

Seismic Instrument Response, Correction for, Fig. 6 Amplitude frequency response of a 1 Hz velocity sensor (top) and an accelerometer (bottom) with a natural frequency of 100 Hz. From left to right, the figures show the sensor response for ground displacement, velocity, and acceleration, respectively. The axes are logarithmic and the horizontal axes show frequency in Hz. The asymptotic

slope for each segment is indicated. Note how one curve translates into another by just adding or subtracting one unit of the slope corresponding to a multiplication or division by frequency. The response curves assume a generator constant $G = 100 \text{ V/(m/s)}$ for the seismometer and $G = 1 \text{ V/(m/s}^2\text{)}$ for the accelerometer. Please note that the vertical scales are different

Seismic Instrument Response, Correction for, Fig. 7 Top: Seismogram of a local earthquake; the position of the maximum amplitude is indicated. The frequency of the maximum amplitude is 1.4 Hz. The signal

is recorded on a broadband station and the amplitude is therefore proportional to ground velocity. Bottom: The amplitude displacement response function. The gain corresponding to the frequency of 1.4 Hz is indicated

taken care of with the $i\omega$ factor so the normalization constant still has to be multiplied with the same number. For example, at 10 Hz, the gain for displacement will be $2\pi \cdot 10\text{s}^{-1} \cdot 3 \cdot 10^7 \text{ counts/ms}^{-1} = 1.88 \cdot 10^9 \text{ counts/m}$.

How to Correct for the Response

In the simplest case, there is only a need to correct for a single amplitude reading. In Fig. 7, a signal from a local earthquake ($M = 5.2$) recorded on a broadband station is seen. Figure 7 shows the corresponding amplitude response curve for displacement. Notice that around 8 Hz, there is a filter cutting off the high frequencies. This filter is part of the sensor electronics and will be represented by poles and zeros in the response function. In the seismogram the maximum amplitude is 1,105,000 counts at a frequency of 1.4 Hz. From the response curve the gain of the system is 8 counts/nm or $8 \cdot 10^9 \text{ counts/m}$. So the maximum ground displacement amplitude is $1,105,000/8 = 138,125 \text{ nm}$. In practical seismology, nm is mostly used for ground motion since it is a more convenient unit than m. In this example, there was no need for a complex response function and the phase

shift was not considered since only one particular amplitude was used.

In the more general case, it is desirable to make instrument correction for the complete seismogram. The seismogram seen in Fig. 7 is proportional to ground velocity in its passband, and a general procedure is therefore needed to calculate the corresponding displacement seismogram. Obviously it is not possible to deal with one frequency at a time and the amplitude and frequency content of the whole signal must be used. In other words, a spectral analysis must be used.

The complex frequency response function $T(\omega)$ is now assumed known and the complex spectra of the input and output signals $x(t)$ and $y(t)$ can be defined as $X(\omega)$ and $Y(\omega)$, respectively, using the definition for the Fourier spectrum (e.g., Oppenheim and Schaffer 1989). Knowing the complete complex output spectrum, the complete complex input spectrum can be obtained:

$$X(\omega) = Y(\omega)/T(\omega) \quad (26)$$

If $T(\omega)$ is a seismic instrument response, the instrument-corrected ground motion spectrum is now obtained, and since $X(\omega)$ is complex, this also includes the correction for phase.

The separate amplitude and phase spectra of the seismic signal can then be obtained as

$$A_{\text{signal}}(\omega) = \sqrt{\text{Re}(X(\omega))^2 + \text{Im}(x(\omega))^2} \quad (27)$$

$$\Phi_{\text{signal}}(\omega) = \tan^{-1} \left(\frac{\text{Im}(X(\omega))}{\text{Re}(X(\omega))} \right) \quad (28)$$

Thus in practice, the ground displacement spectrum would be calculated by taking the complex Fourier spectrum of the output signal and dividing it with the complex displacement response function and finally taking the absolute part of the complex ground displacement spectrum. This is basically what is done to calculate source spectra for earthquakes (Havskov and Ottemöller 2010).

All of this could of course easily have been done with the corresponding noncomplex equations since, so far, the phase information has not been used and usually phase spectra for earthquake signals are not used. However, the next step is to obtain the true ground displacement time domain signal instead of the frequency domain signal. With the knowledge about Fourier transforms, this is now easy, since, when all the frequency domain coefficients or the spectrum has been calculated, the corresponding time domain signal can be generated by the inverse Fourier transform. Since the corrected signal consists of a sum of cosine signals with different phases, each of them delayed differently due to the instrument response, the shape of the output signal will depend on the phase correction. So now life is easy, since the corrected complex displacement spectrum is already corrected for phase and the ground motion can be obtained as

$$x(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} Y(\omega)/T(\omega) \cdot e^{i\omega t} d\omega \quad (29)$$

While it is possible to use only half of the positive frequencies for making the amplitude spectrum, both positive and negative frequencies must be used for the inverse transformation. Normalization constants of the Fourier transform can be defined in different ways, but if the same routine

is used for both forward and inverse, the normalization constants will cancel out. In practice, since the signal consists of discrete numbers, the spectrum also is done with discrete numbers; see, e.g., Oppenheim and Schaffer (1989).

Response Correction in Practice

In theory it is possible to recover the ground motion (displacement, velocity, or acceleration) at any frequency knowing the instrument response. In practice, one has to be careful to only do this in the frequency band where the instrument records real ground motion and not just electronic noise, since the instrument correction then becomes unstable and the output has nothing to do with the real seismic signal. Figure 8 shows an example.

The figure shows the influence of filtering, when estimating the ground displacement signal. In the frequency band 1–10 Hz, the signal looks very much like the original signal although a bit more low frequency, since it is converted to displacement and can nearly be considered an integration of the original signal. In the 0.1–10 Hz range, the earthquake signal almost disappears in the microseismic background noise. Why is this signal considered seismic noise and not instrumental generated noise? First, the earthquake signal has about the same amplitude as above; second, it “looks” like seismic background noise; and third, the amplitude at 1,290 nm is at a period of 5 s (peak amplitude of microseismic noise) which looks reasonable compared to worldwide observations. Note that this is how the earthquake signal would have looked being recorded on a broadband sensor, hardly noticeable. The last trace shows the calculation of the displacement without filtering so the lowest frequency used is $1/T$, where T is the length of the window, here 80 s (only 65 s shown) so $f = 0.0125$ Hz. The amplitude is now more than 50,000 nm and the signal looks “funny.” The large amplitude obviously cannot be right since the microseismic noise has its largest amplitude around 3–8 s and it was 1,290 nm. So this is a clear case of trying to make a displacement signal at frequencies lower than where seismic signals exist in the data.

Seismic Instrument Response, Correction for, Fig. 8 Instrument corrections in different filter bands. The top trace is the original recording of a small earthquake with a 1 Hz seismometer. The three bottom traces have been converted to displacement using different

filters. The third trace from the top shows harmonic waves at a frequency of about 0.2–0.3 Hz which is typical microseismic background noise originating in the ocean. The amplitudes to the right are maximum amplitudes (Figure from Havskov and Alguacil (2010))

Seismic Instrument Response, Correction for, Fig. 9 Acceleration and displacement. The seismogram in the figure is the first few seconds of a P-wave. On the site there is also an accelerometer installed (A) next to the seismometer (S). The top traces show the original records in counts. The signal from the seismometer is similar to

the accelerometer signal but of lower dominant frequencies, and the amplitudes are different. The middle traces show the two signals converted to accelerations and the bottom traces converted to displacement (frequency band 1–20 Hz) (Figure from Havskov and Alguacil (2010))

The ratio of the displacement gain for a 1 Hz seismometer at 1 Hz and 0.0125 Hz is $1/0.0125^3 = 5 \cdot 10^5$. In other words, if the gain at 1 Hz is 1.0, the signal must be multiplied by 1.0 to get the displacement, while at 0.0125 Hz, it must be multiplied by $5 \cdot 10^5$. So any tiny amount of instrumental noise present at low frequencies will blow up in the instrument correction. In the above example, it seems that the displacement signal can be recovered down to 0.1 Hz with a 1.0 Hz sensor.

Engineers often think accelerometers are the only instrument to use and seismologist normally will only use the weak motion velocity sensor (seismometer). However, knowing the response curve and the limitation in the data, it does not really matter which instrument is used; see Fig. 9. In this example, a seismic signal has been recorded on a 1 Hz seismometer and an accelerometer at the same site, and using the respective response function, both signals have been converted to displacement and acceleration. The only limitation is that a seismometer may get saturated by a strong motion and an accelerometer will not be sensitive enough for recording weak motions (e.g., from distant earthquakes).

The corrected signals are now very similar and of the same amplitude. This example clearly demonstrates that, with modern instruments and processing techniques, both accelerometers and seismometers can be used to get the same result.

Summary

Recorded seismic signals represent a number proportional with the ground motion. The most common seismic stations have a velocity sensor with an output proportional to ground velocity in some frequency band and/or an acceleration sensor with output proportional with ground acceleration in combination with a digital recorder. All these elements will have some frequency dependence and it has been shown:

- How to calculate the system frequency response
- How to correct for both the sensor and the recorder in order to obtain the true ground

motion, whether in displacement, velocity, or acceleration

- How the noise influences the correction making it necessary to limit the correction to a particular frequency range

Introduction

It is observed that earthquakes, particularly those of large magnitudes, can cause significant damage to structures over a large region surrounding the rupture zone of earthquakes. The top three costliest earthquakes in the world during 1980–2012 are the Mw 9.0 Tohoku-Oki earthquake (2011), Mw 6.8 Kobe earthquake (1995), and Mw 6.7 Northridge earthquake (1994) causing overall economic losses when occurred about \$210B, \$100B, and \$44B respectively (III 2013). The structures those are damaged due to earthquakes are not only buildings, bridges, etc., but also utilities like water, gas and sewer lines, and lifelines like train tracks and roads. The earthquakes also cause landslides due to movement of grounds or liquefaction due to loss of strength of the soil underneath the structures. In addition, earthquakes can cause fire and tsunami leading to significant damage to structures. All the historical losses illustrate that the potential for earthquake loss can be significant in a specific region or to portfolio of buildings for insurance companies. Hence it is important for the federal and state governments or for the insurance companies to estimate accurately the seismic losses to the built environment or to the insured properties to manage earthquake risks.

The performance of buildings nowadays is expressed in terms of monetary loss due to damage, downtime, and number of injuries including fatalities due to earthquakes. See, for example, performance-based earthquake engineering (PBEE) framework developed by Pacific Earthquake Engineering Research (PEER) center (Cornell and Krawinkler 2000) or that developed by ATC-58 (2011). The loss assessment of buildings is often carried out using a vulnerability function (also known as damage function), which defines the distribution of the ratio of the building loss to the building value as a function of ground-motion (GM) intensities. In this chapter, different approaches of development of building vulnerability functions (VF) will be discussed. This will be followed by calculations of the risk of building loss due to earthquakes by integrating the seismic hazard results with the building VFs.

This provides monetary losses to buildings in terms of the average annual loss (AAL) and losses at various return periods.

In 1985, Applied Technology Council (ATC) first published a comprehensive report (ATC-13 1985) to estimate the earthquake loss of existing buildings by developing a suite of VFs based on expert opinions. ATC considered this approach since very limited earthquake damage or loss data were available at that time. The report developed earthquake loss estimates as a function of Modified Mercalli Intensity (MMI) for different facility classes (e.g., low-rise wood frame). Recently, Global Earthquake Model (GEM) project has also followed a similar approach (Jaiswal et al. 2013) for developing VFs.

Professor Karl Steinbrugge based on engineering investigations, data collection, and field studies of earthquake-damaged buildings developed the first, well-accepted VFs providing an estimate of the functional relationships between building damage and earthquake intensities (Steinbrugge 1982). These functions provided a firsthand insight to the damageability of buildings to the insurance companies in the 1990s. Since engineers were interested primarily in the life safety of buildings till the end of the twentieth century, there was limited interest among the engineers to compile the damage data of all the slightly and moderately damaged buildings for assessing performance of buildings in earthquakes. Northridge earthquake (1994) was the first earthquake that provided a large number of insurance claims data, which are used for performance assessment of single-family low-rise wood-frame buildings in high seismic zones of California, for example, Los Angeles and San Francisco (Wesson et al. 2004).

In 1999, the Federal Emergency Management Agency (FEMA) first published a comprehensive methodology to calculate *analytically* earthquake damage of model buildings for a given peak response to estimate potential losses from earthquakes (HAZUS 2003). Later on, the assembly-based vulnerability (ABV) was developed by Porter et al. (2001), and this was adopted by the Consortium of Universities for Research in Earthquake Engineering (CUREE) project (2001)

for developing vulnerability functions for wood-frame buildings. This is a significantly improved analytical approach over the HAZUS. The CUREE approach, however, did not consider more realistic representations of structures (e.g., 2D/3D nonlinear FEM model as has been considered lately in the latest PEER or ATC projects), has limited set of fragility functions compared to those considered lately in the ATC-58 project (2011), and also did not consider the correlation of response or damage between different components of buildings for accurate estimation of variability of total loss of buildings.

Recently, researchers are focused on developing analytical VFs based on detailed nonlinear analysis of buildings. For example, PEER (2011) considered 3D models of 40+ story tall buildings (Shome et al. 2014; Ramirez and Miranda 2009; Shome and Bazzurro 2009), and many others have considered 2D plane frame model for loss estimation of buildings. In addition, ATC-58 (2011) has developed a number of approaches – simple to very detailed and complex – for loss assessment of buildings. Majority of the researchers has adopted a *story-based loss assessment procedure* to take into account the variation in loss over the height, which is particularly important for mid- to high-rise buildings. All these researchers have considered a large number of ground-motion records for nonlinear response analysis of buildings, and a few of those made appropriate correction to the response results because of possible introduction of bias due to scaling of those records for nonlinear analysis (Haselton 2009). It is observed that standard approach of scaling does not take into account dependence of building response on the spectral shape and this introduces bias in the response results. In this context, the framework developed by Jayaram et al. (2012) will be discussed in detail. This approach considered story-based loss assessment, took into account the bias in the response results due to spectral shape, and considered correlation of response, damage, and repair cost of different components of buildings at different stories.

It is well known that there is significant uncertainty in the estimation of loss results and this

uncertainty can be divided into two different categories: (1) aleatory and (2) epistemic (Benjamin and Cornell 1970). Aleatory uncertainty is the inherent variability in the physical system; it is stochastic and cannot be reduced by improving the current approach of loss estimation. Epistemic uncertainty, on the other hand, is associated with lack of knowledge; it can be subjective and is reducible with additional information. There are significant epistemic uncertainties associated with the loss estimates due to uncertainty in the estimation of different parameters, and this should be considered in the decision-making process. FEMA-355F (2000) and ATC-58 (2011) have recommended typical uncertainties of a large number of parameters based on extensive research, and Jayaram et al. (2012) have developed a comprehensive approach to estimate epistemic uncertainty of VFs based on the uncertainty of those parameters.

Methodology

The seismic loss estimation of buildings is dependent on the lateral load resistance characteristics of buildings. Since building codes are being improved over the years, load resistance is dependent on the age of buildings. In addition, the resistance also depends on: (1) construction class (e.g., steel moment-resisting frame), (2) occupancy class (e.g., residential), and (3) region (e.g., high seismic regions in California). Although lateral resistance ideally should not depend on the occupancy class, it is generally observed that commercial buildings are generally well designed and constructed than residential buildings leading to better lateral resistance capacity of those buildings. The loss estimation of portfolio of buildings uses this type of generic information (e.g., HAZUS 2003) by grouping the buildings with similar load resistance capacities. The loss estimation of individual buildings (e.g., ATC-58 2011), on the other hand, uses the detailed building information to estimate accurately the lateral load resistance capacity of buildings for calculating seismic losses. The seismic loss estimation approaches that will be discussed

Seismic Loss Assessment, Fig. 1 Illustrative five-parameter Beta distribution

in this chapter can be applied easily for loss estimation of both portfolios and individual buildings. The VFs are developed based on mainly three approaches: (1) empirical approach which is generally expert-opinion-based development, (2) observation-based approach which is based on building loss data, and (3) analytical approach. All these approaches as well as the advantages and disadvantages will be discussed here.

Earthquakes not only cause damage to structural and nonstructural components of buildings but also damage building contents, such as furnitures, and cause closure of buildings. The closure incurs losses due to the expenses to the occupants for temporary rents or hotel stay (called additional living expenses, ALE) or loss of income to businesses (called business interruption, BI, loss). The losses to contents and due to closure of buildings will not be discussed in this chapter. This chapter will focus only on the loss due to *property damage of buildings from shaking of earthquakes*.

Loss Distribution

Since there is significant uncertainty (aleatory and epistemic) in estimating building losses at a given intensity of GM, VFs provide the loss distribution parameters as a function of intensities. It is generally assumed that the loss distribution can be represented by parametric distribution

model, and Beta distribution is widely used for building loss calculations following ATC-13 recommendation (1985). The parameters of the distribution can be estimated from the mean and variance of the sample losses (Benjamin and Cornell 1970). The insurance claims data, however, show that the Beta distribution combined with Dirac delta functions at 0 % loss and 100 % loss to model the probabilities of zero (F_0) and complete (F_I) loss fits the observed loss distribution data better. In addition, insurance companies generally pay to completely replace a property (i.e., 100 % loss) beyond a particular threshold (α) of loss (e.g., 70 % loss). Hence, more accurate representation of distribution requires three additional parameters, which are F_0 , F_I , and α , in addition to the conventional mean and variance. The 5-parameter distribution for losses is shown in Fig. 1 for illustration. Note that this type of distribution may be more appropriate to model the insurance losses. The methodology for estimating the five parameters of the distribution from loss data will be discussed in detail later on.

Seismic Risk

Seismic risk assessment of buildings requires estimating the probability of losses for all the possible future earthquakes over a specified period of time or estimating losses for a scenario earthquake. The scenario earthquake can be a

historical earthquake, or maximum credible earthquake (MCE), or standard design basis earthquake (DBE), or more frequent service level earthquake (SLE). The standard risk management of buildings entails estimation of average annual loss (AAL) for all the possible earthquakes to determine the insurance premium of buildings. This is the amount of modeled premium that an insurer needs to collect in order to cover the average loss over time. The other risk quantity that is commonly employed is estimation of probability of exceeding certain loss for all the possible earthquakes. When this is estimated for different amount of losses, the result is known in the insurance industry as the exceedance probability or EP curve. The scenario loss for a given earthquake, on the other hand, is useful for deterministic seismic risk management by estimating the Probable Maximum Loss (PML). PML is the largest possible loss which may occur, in regard to a particular risk, given the worst combination of circumstances. Traditionally, PML is the expected shake damage loss given the maximum size earthquake. There is, however, considerable uncertainty over the severity of loss that might arise under a broad variety of events. So an improved PML is a conservative deterministic upper bound, which is typically 90 % upper confidence bound on the portfolio loss from a risk-based MCE, for example, 2,475-year return period event on a fault. All these risk calculations require distribution of building loss as a function of intensity of GM and this is obtained by developing the VFs of buildings. The following section will discuss different approaches of development of VFs.

Empirical Approach: Expert-Opinion-Based Vulnerability Functions

There is significant advantage in developing expert-opinion-based VFs. This approach can be followed to develop VFs relatively quickly and easily without requiring any loss data or developing any analytical approach. Researchers over the years have followed primarily two approaches for developing VFs: (1) Delphi method which was

followed by Applied Technology Council (ATC) in the ATC-13 (1985) and (2) Cook's approach followed recently in PAGER and GEM project (Jaiswal et al. 2013). Although the information generated from these approaches may not be very reliable, this type of approach will continue to be used in other projects in the future because of ease in developing VFs when information or resource is limited.

ATC-13 (1985) Approach

One of the first systematic attempts of developing building vulnerability was carried out by ATC-13 for assessing seismic risk in the state of California for the Seismic Safety Commission (SSC). The project was funded by the Federal Emergency Management Agency (FEMA). Since very limited earthquake loss data was available at that time and there was no acceptable analytical approach available for estimating building loss calculations, ATC derived VFs based on experience and judgment of the experts – structural engineers, builders, and the like – by estimating the expected percentage of damage of typical buildings for a specific construction type when these buildings are subjected to a Modified Mercalli Intensity (MMI). Based on personal knowledge and experience, the experts responded to a formal questionnaire with their best estimates of percent physical damage or damage ratio.

In order to develop the VFs, ATC established an advisory project engineering panel (PEP) providing necessary feedback in order to develop consensus of damage or loss estimates of different facility classes. This was modeled after the Delphi method for expert-opinion solicitations, which was originally developed for the Air Force by RAND Corporation in the 1950s. The tasks in Delphi method consist of formulating questionnaires, getting answers to those from experts, iterating the answers one or more times, and aggregating the responses by following a suitable statistical approach. The questionnaire asked each expert to provide low, best, and high estimates of the damage ratio for different construction classes or engineering facilities at different MMI. In addition, the experts were also asked to provide their level of experience with the

Seismic Loss Assessment,

Fig. 2 Vulnerability functions of single-family wood-frame buildings in California. (a) Mean damage ratio (*MDR*). (b) Coefficient of variation (*CoV*)

construction class and the degree of uncertainty in their estimates. Subsequently, two other sets of questionnaires were developed in order to reach a consensus on the estimation of different damage estimates. The questionnaire results were processed to develop damage probability matrices (DPM) by fitting Beta distribution to those results. In DPM, the damage to a construction class for a given intensity is described by a series of damage states (DS) and the probability that the DS will occur at that intensity. The VF of single-family wood-frame buildings in California following this approach is shown in Fig. 2 for illustration.

Because it was the first systematic attempt to develop VFs, ATC-13 quickly became the standard for assessing earthquake risk of buildings.

Catastrophe modelers and risk engineers adopted the ATC-13 damage curves until the 1994 Northridge earthquake. It will be shown later on that there is significant difference in the results based on ATC-13 and that observed in the Northridge earthquake. In addition, the ATC-13 approach is subjective. The damage functions from this approach are based exclusively on the opinion of experts. For this reason, it is difficult to calibrate or modify those in order to incorporate new data or new design (e.g., adjustment for new seismic code or other seismic regions). These functions can also be biased as observed in the Northridge earthquake. Hence, in the recent years, researchers have focused on developing VFs either based on observed building-level damage data (Wesson et al. 2004) or from

analytical approaches. This approach combines the experimental damage data and the observed damage data of different components of buildings (Jayaram et al. 2012).

GEM/PAGER Approach

Recently, US Geological Survey (USGS) has adopted Cook's model for developing VFs for the PAGER system and for the GEM project (Jaiswal et al. 2013). This approach involves identifying experts, constructing seed and target questions, eliciting expert judgments, and combining multiple judgments. In this approach, unlike the Delphi approach (adopted by ATC-13), the judgment of scoring is calibrated objectively and classical statistical test is employed for hypothesis testing of the scores. This involves assigning weight to an expert based on two separate scores: (1) *calibration score* which measures the accuracy of the scores by the experts based on background reference density functions of the scores and (2) *information score* which represents the degree with which the distribution of the expert is concentrated with respect to some background distribution. The product of these two scores is the overall score of each of the experts. Since the weights can be recomputed objectively with new observation or addition of new experts, the weights can be recomputed in the future for updating the VFs.

Observation-Based Approach: Vulnerability Functions from Building Damage Data

The most direct approach of developing the VFs would be based on building damage data observed in historical earthquakes. This approach requires damage data of large number of buildings for different construction classes, height, age, and other characteristics, which are important in defining lateral load resistance of buildings. If the damage data is based on detailed inspection of buildings following earthquakes, VFs can be developed accurately. But this requires significant amount of time and resources

and so this type of data is not available in sufficient quantity for developing the VFs. On the other hand, insurance claims data (e.g., those from Northridge earthquake) can provide a large quantity of damage data, which can be used for estimating VFs. But these data typically contain limited information about the buildings (typically provides construction class – primarily materials of construction, e.g., steel, etc., height, and age).

The earliest attempt in developing VFs following this approach was by Steinbrugge (1982). The VFs were developed based on limited damage data for a handful of earthquakes. Since insurance industry was not active in collecting damage data before the 1990s and engineers were focused on studying a few important damaged buildings following earthquakes, Steinbrugge applied his experience and judgment in order to develop the functions based on limited damage data that he collected over the years from small number of earthquakes. The developed VF for single-family wood-frame buildings is shown in Fig. 2. The results show that the vulnerability of residential wood-frame buildings is significantly higher than that predicted by ATC-13 at lower intensities. This function was used extensively by the insurance companies in the 1980s–1990s as a guideline for managing earthquake risks. Later on, this function will be compared with that based on extensive damage data from Northridge earthquake.

In this section, Northridge insurance claims data, which lacks detailed information on the lateral load resistance characteristics of buildings, will be used for developing the VF. The other type of data, which would be a preferred one, is the damage data that provides the detailed lateral load resistance characteristics of buildings. An example on this would be the data of fractured connections of 167 welded steel moment-frame (SMF) buildings collected in the SAC joint venture project. This data was collected in a very detailed and systematic way following Northridge earthquake, and those data were used for developing empirical VFs for building loss calculations in FEMA-351 Rapid Method (Bonowitz and Maison 2003). The project inspected about 18,000 connections and

found that 13 % of those had some kind of damage. Although this approach provided very accurate information about the performance of welded connections of SMF buildings, seismic loss estimation requires repair cost of those connections as well as other structural and nonstructural components of those buildings. Note that the value of the nonstructural components can be more than 70 % of total building value and so the repair cost of these components is significant, particularly at low intensities. Since damage of nonstructural components were not collected, the empirical VF developed in SAC project is primarily for the structural components, and the VF will provide a low estimate of damage at low intensities. In addition, the uncertainty in the damage or loss of buildings at a given intensity cannot be estimated from this limited data, and this information is essential for seismic risk calculations.

Since insurance claims data lacks detailed building information, the VFs developed from this data are for a broad category of buildings, like low-rise wood-frame buildings constructed in the era of moderately developed building code (e.g., 1950–1975 in high seismic regions in California). This would lead to higher uncertainty in the estimation of losses relative to the losses for a specific building. The other issue with the insurance claims data is that the data captures losses only after applying the deductibles (known as gross loss). Hence the building loss is partially known from insurance claims data (formally known as “censored” data), and this missing information is critical for accurate estimation of building vulnerabilities at low intensities.

Development of Vulnerability Functions Based on Claims Data

In this section, insurance claims data will be used for developing VFs, which estimates the probability distribution of building loss as a function of ground-motion intensity. This approach is illustrated here by using the Northridge claims data, which is even today the best source of a large number of high-quality insurance claims data for earthquakes. The data were available only by zip codes and provided the claim amount, value of

the structure, year of construction of the buildings, and the construction class. The scatter plot of insurance loss data for single-family wood-frame dwellings (SFD) constructed after 1975 is shown in Fig. 3a, and the same for steel moment-frame (SMF) buildings based on detailed inspection of beam-column connections is shown in Fig. 3b for visual comparison of the trend and uncertainty in these two data sets. The figure illustrates that the uncertainty conditioned on earthquake intensity (here PGA for SFD and $S_a(T = 2 \text{ s})$ for SMF) is very high. The vertical stripe of data in the Fig. 3a represents the variation of loss ratio in a specific zip code since Northridge data is available only at the zip code level. Note that although the insurance claims data provides losses for content and additional living expenses (ALE), those are not considered in this section. The building loss data here includes damage to the structural as well as nonstructural components of buildings.

Since the Northridge losses are available by zip code, Wesson et al. (2004) estimated loss distribution by zip code by fitting a 2-parameter Gamma distribution to the claims data. Since insurance data does not capture the losses below deductible, the maximum likelihood approach was followed for estimating the parameters with the constraint that the fraction of losses below deductible must be equal to the observed fraction of no loss. The parameters of the distribution for each of those zip codes are then fitted independently against the intensity measure to get the distribution of loss as a function of intensity measure. The VFs based on this approach are shown in Fig. 2. It is observed that there is significant difference in the results between the vulnerability functions based on Northridge insurance claims data and that estimated earlier in ATC-13 following expert opinion or by Steinbrugge based on limited damage data.

A more direct approach for the estimation of the distribution parameter would be to estimate those directly from the data by grouping those as a function of intensity. In the earlier approach, since each of the parameters of the distribution was fitted independently, the correlation between the parameters was not preserved. In addition, the

Seismic Loss Assessment,

Fig. 3 Distribution of damage ratio (ratio of claims amount or repair cost and building replacement cost) distribution as a function earthquake intensity as observed in Northridge earthquake. (a) Post-75 single-family wood-frame buildings. (b) Steel-frame buildings inspected in SAC project

regression analysis gave equal weight to all the parameters for each of the zip codes irrespective of the number of data points in the zip codes. Since Beta distribution is commonly employed for describing the earthquake loss distribution and a five-parameter Beta distribution is deemed to be the most suitable for modeling seismic loss distribution, the fitting of five-parameter distribution model to the loss data will be discussed here. The five parameters of the distribution are: mean, variance, probability of no loss (F_0), probability of complete loss (F_1), and the threshold (α) beyond which losses are considered to be 100 % by insurance companies. The parameters of the probability distribution can be estimated by using two methodologies, namely, the method of moments and the maximum likelihood approach. Since the insurance loss data is available after applying the insurance limits and deductibles,

the method of moments is not suitable for this type of data. Hence *maximum likelihood approach* will be followed to estimate the parameters (see Shome et al. 2012 for details).

In general, the building VFs based on observed damage/loss data from one region cannot be directly extrapolated to other regions since the building design and construction practice varies among different regions. Since the frequency of large-magnitude earthquakes is small and the occurrence of those events near large population center is even rarer, it is not possible to get a large number of damage data for different construction classes in order to develop VFs. Also this approach needs high-quality data, i.e., building-level loss results like those obtained in 1994 Northridge earthquake. The number of data should be high for estimating VFs with high confidence.

Maximum Likelihood Estimation (MLE) of Parameters

The objective here is to estimate the parameters of the five-parameter Beta distribution for the actual loss paid by the building owners for repairing buildings (i.e., distribution for ground-up (GU) loss). The GU loss is computed by adding the gross loss, the deductible, and the losses beyond the limits if applied. But this cannot be done for the cases when the gross loss equals zero. This is a typical case of left-censored data set where the ground-up losses are accurate above deductible, but the data

below deductible is not available and is reported as zero. If F_0 is simply estimated as the fraction of data points with zero ground-up loss, F_0 will be severely overestimated when the deductibles are large particularly at low intensities. Note that the data is right censored as well because losses beyond the insurance policy limits are truncated to the limit. This is, however, much rarer since it only occurs at very large damage ratios induced by very high-intensity GM.

The density function for damage ratio $f(D_i)$ at a given intensity equals the following:

$$f(D_i) = \begin{cases} F_0 & \text{for } D_i = 0 \\ F_0 + (1 - F_0 - F_1)B_{PDF}(D_i, a, b) & \text{for } 0 < D_i < \alpha \\ [F_1 + (1 - F_0 - F_1)(1 - B_{CDF}(\alpha, a, b))] & \text{for } D_i \geq \alpha \end{cases} \quad (1)$$

where:

α = The threshold beyond which losses are treated as 100 %. Note that this is governed by the underwriting policy of an insurance company.

$B_{CDF}(D_i, a, b)$ = Beta cumulative distribution function (CDF) corresponding to sample damage ratio D_i (=the ratio of the loss to the building's value).

$B_{PDF}(\cdot)$ = Beta probability density function (PDF).

a and b = Parameters for the Beta distribution of the sample damage ratios for a GM intensity bin.

Hence the likelihood of observing damage ratios D_i s equals:

$$L = \left[\prod_{D_i=0} F_0 + (1 - F_0 - F_1)B_{CDF}(ded_i, a, b) \right] \left[\prod_{D_i \geq \alpha} F_1 + (1 - F_0 - F_1)(1 - B_{CDF}(\alpha, a, b)) \right] \left[\prod_{D_i \in (0, \alpha)} F_0 + (1 - F_0 - F_1)B_{PDF}(D_i, a, b) \right] \quad (2)$$

where the parameters, F_0 and F_1 , correspond to a range of GM intensities for which loss data is accumulated for fitting and these parameters are estimated by maximizing L . The first term in the likelihood estimate corresponds to data points where the observed damage ratio equals zero. This includes likelihood of damage ratio less than deductible ded_i , but reported as zero in the claims dataset, and the true zero damage. The second term corresponds to data points where the observed damage ratio equals 1. This corresponds to the likelihood of observing complete loss and the losses above the threshold, α . The third term corresponds to the rest of the data points where the damage ratio is more than deductible, but less than α . The parameters of the distribution F_0 , F_1 , a , and b are obtained by maximizing the likelihood of observing all the damages, D_i , which is shown in Eq. 2 as the product of likelihood of the damages.

The results of fit of the five-parameter distribution to the Northridge loss data at high-intensity GM are shown in Fig. 4. The claims data used for fitting the distribution is from a number of insurance companies and the information of the threshold (α) is not available from those companies. Hence for simplicity, it is assumed that α equals to 100 % damage.

Seismic Loss Assessment,

Fig. 4 Comparison of distribution of loss at high-intensity ground motion between the data and MLE fit

The results show that the fitting captures well the objective of probability mass at zero and 100 % damage. Note that it would be difficult to estimate reliably all the parameters of the distribution when data is limited. In those cases, it is advisable to bring in other sources of data to define the loss distribution. For example, one can use building collapse results – analytical and/or experimental – to define F_I of a specific building or a class of buildings.

Analytical Approach of Development of Vulnerability Functions

There is limited building damage data from earthquakes and that too from small number of construction classes. In addition, building damage characteristics based on the damage data from one region may not be extrapolated to other regions. Hence, VFs for majority of construction classes in most of the regions in the world can be developed only from an analytical approach. Hence HAZUS (2003) first developed a comprehensive analytical methodology to estimate the building seismic losses. HAZUS adopted capacity spectrum method to estimate response of *generic buildings* and estimated only *mean* loss based on damage of different building components. Later on, CUREE-Caltech (2001) developed the assembly-based vulnerability (ABV) methodology for developing *building-specific* VFs. In this

approach, the damage is calculated for the individual building assemblies, e.g., partition wall, based on the response results from *nonlinear time-history analysis* of the model buildings to estimate *mean and variance* of damage of the model buildings as a function of GM intensity. The individual buildings in this approach were represented by deterministic simplified structural models, where building components were idealized as springs and masses. Recently, Jayaram et al. (2012) have developed a systematic simulation approach based on the PEER-PBEE loss assessment framework to develop building-specific VFs from component-level damage at each story of buildings. In this approach, the total building loss is estimated by using the response from detailed nonlinear time-history analysis of buildings. The approach took into account the dependence of response on S_a at multiple periods, the correlation of losses between different components to improve the estimation of uncertainty of losses, and on captured the effects of epistemic and aleatory uncertainties of different parameters considered in loss calculations, such as GMs, structural response parameters, loss costs, etc. All these steps help to get the unbiased loss due to earthquakes and quantify accurately the uncertainty in the loss estimates.

The analytical loss calculation in general consists of (1) repair cost of different building components associated with a damage state or cost

due to demolition, (2) damage state given a demand parameter (EDP), and (3) EDP given an intensity of GM. A brief description of these parameters is given below and the details can be found in HAZUS (2003).

Building Components

In order to carry out the seismic loss calculations, building components are divided broadly into two categories: structural and nonstructural. The loss estimation approach either estimates damage of the individual components (e.g., CUREE-Caltech 2001) or damage of a group of components or subsystems (e.g., HAZUS 2003). The structural component (SD) resists gravity, earthquake, wind, and other types of loads. This includes components like columns, beams, load-bearing walls, etc. For buildings planned by design professionals, the structural components are typically designed and tailored to building-specific configurations and loading conditions. The nonstructural components include a large variety of architectural, mechanical, and electrical components, which can be further divided into as either “drift-sensitive” (NSD) (e.g., non-load-bearing partition walls, exterior curtain walls, etc.) or “acceleration-sensitive” (NSA) components (e.g., suspended ceilings, HVAC systems, etc.). These components are usually neither designed by the professionals nor tailored to specific buildings even when designed. These are tested under some generic load conditions to satisfy the acceptability criteria of the building codes under some idealized conditions. Hence the uncertainty in the performance of structural components is relatively low when designed and constructed by professionals compared to those of the nonstructural components. Drift is used to predict the damage states of the SD and the NSD subsystems or components. Acceleration, on the other hand, is used to predict the damage states of the NSA components.

Damage States

The damage state of each subsystem or component represents a consequence in terms of repair

for the type and the severity associated with that state. This is predicted based on the fragility functions of the subsystem or component. The damage states are defined in HAZUS (2003) and these are none, minor (DS1), moderate (DS2), extensive (DS3), and complete damage (DS4). For example, moderate structural damage of concrete shear-wall buildings is defined by the diagonal cracks on most of the shear-wall surfaces and large diagonal cracks with spalling of concrete at the wall ends of some shear walls. The moderate damage of the NSD components or subsystems represents large and extensive cracks of the partition walls requiring repair and repainting as well as replacement of a few walls. The moderate damage state of the NSA subsystem or component represents extensive falling of the suspended-ceiling tiles with disconnected and/or buckled ceiling support framing (T-bars) at a few locations.

Repair Costs

The loss from earthquakes is associated with the repair due to damage of different components or subsystems as well as building replacement cost associated with demolition and collapse. The uncertainty in repair cost arises primarily due to lack of information about the component. The cost of repair works is generally significantly higher than the cost of new construction, and this is more significant for the structural components than the nonstructural components. For example, the repair of beam-column connections of the structural component requires removing the suspended ceilings, inspection of the joints which may require non-destructive testing, closure of part of the floor of the building, etc. All these expenses have to be incurred on top of the repair cost of the connections. Insurance claims data also suggest relatively higher uncertainty in repair cost at low intensities. In order to estimate the repair cost, it is generally assumed that the insurer will pay the cost of repair or replacement of the damaged buildings with the materials of like kind and quality without any deduction for depreciation, which is called *replacement cost method* for valuation.

HAZUS-Based Vulnerability

The HAZUS methodology is developed to estimate losses for different federal, state, and local agencies for planning earthquake risk mitigation, emergency preparedness, and many other uses. Although the methodology can be used to estimate losses for individual buildings, it is developed to estimate losses of portfolio of buildings distributed over a large region. The methodology provides an estimate of the probability of mean loss for none, slight, moderate, extensive, and complete damage of building components at a given level of ground shaking. The building damage characteristic is defined by the following curves: (1) fragility curves that describe the probability of reaching or exceeding different states of damage given the peak-building response and (2) building capacity (pushover) curves that are used to determine the peak-building response for the demand spectrum.

Fragility Functions

The fragility curve is defined by a median value of the engineering demand parameter (EDP), which is, for example, spectral displacement in HAZUS and maximum interstory drift ratio (IDR) in Jayaram et al. 2012, and by the variability associated with the estimation of that damage state for that EDP. The median EDP corresponds to the threshold of the damage state. The curve is assumed to follow the cumulative lognormal distribution function as shown below:

$$P(DS \geq ds_i | EDP) = \Phi\left(\frac{\ln(EDP/\mu)}{\beta}\right) \quad (3)$$

where μ denotes the median value of EDP at which building component or subsystem reaches the threshold of the damage state ds_i , β denotes the corresponding dispersion, and $\Phi(\cdot)$ is the cumulative density function for standard normal distribution. The dispersion considers (1) uncertainty in the damage state threshold, (2) variability in the capacity (response) of buildings, and (3) uncertainty in building response or EDP due to the spatial variability of ground motion.

Seismic Loss Assessment, Fig. 5 Mean fragility functions and its uncertainty for extensive damage of nonstructural drift-sensitive subsystem (NSD)

The component fragility functions are estimated from the results of laboratory experiments or from observed damage data. Since there is limited observed damage data or experimental data, past studies recommended fragility functions primarily based on engineering judgment (e.g., HAZUS). Recently, ATC-58 (2011) has made significant effort to develop a suite of fragility functions so that loss calculations can be carried out in day-to-day building design work. Also Network for Earthquake Engineering Simulation (NEES) Program is actively pursuing experimental research (<http://www.nees-nonstructural.org/>) to develop fragility functions for different nonstructural components of buildings. All these research provide a range of fragility functions giving an estimate of the mean and the standard deviation of the fragility functions. The mean fragility function for extensive damage of the generic NSD subsystem, which is an assembly of a number of components such as partitions, exterior glazing systems, etc., is shown in Fig. 5. The epistemic uncertainty in the estimation of the fragility function for that damage state is shown by the 90 % confidence band.

Building Response Calculations

The building responses in HAZUS are estimated based on the *capacity spectrum method* (CSM). The building capacity curve (also known as a

Seismic Loss Assessment,

Fig. 6 Example building capacity curve, demand spectrum, and building response for wood-frame buildings in California for input spectrum from M7 earthquake on Hayward fault at a site close to the fault

pushover curve) describes the lateral load resistance of a building as a function of its characteristic lateral displacement. The curve is derived from the results of static-equivalent base shear and roof displacement and is defined by three control points: (1) design capacity, (2) yield capacity, and (3) ultimate capacity as shown in Fig. 6. It is assumed that the building capacity will have a range of possible properties and those are lognormally distributed as a function of the ultimate capacity. The peak-building response is the intersection of the building capacity curve and the response spectrum, which defines the seismic demand. Since buildings go beyond its elastic limit, the demand spectrum defined by the elastic damping is reduced due to the higher effective damping. The effective damping includes both the elastic damping and the hysteretic damping associated with the post-yield cyclic response of buildings. Figure 6 illustrates the capacity curve, demand spectrum curve, and the peak-building response at the point of intersection of those curves. The main drawback of CSM is that the MDOF structures are idealized by an equivalent SDOF system using an increased period and damping in order to estimate the seismic demand of the MDOF structures by the capacity spectrum approach. In addition, this method is a nonlinear static procedure, whereas the nonlinear time-history analysis generally provides a more accurate estimation of building

response particularly at higher intensities. Hence this approach may not be suitable for mid-rise and high-rise buildings and for types of buildings at high intensities.

Building Loss Calculations

The fragility curves define all the four damage states for each of the three building subsystems based on the EDPs estimated from the intersection of the capacity curve and the seismic demand curve. It is assumed that the nonstructural damage states are independent of structural damage states. The repair cost is estimated based on the damage of different subsystems of buildings. Note that although the results from HAZUS loss estimation methodology are intended to assess the socioeconomic impact of earthquakes in a region, the result has a number of limitations. Earthquake impact on a society is a very complex process and the economic consequences cannot be considered in a simplistic approach. The dollar losses are calculated for all the three coverages: (1) building repair and replacement costs, (2) contents losses, and (3) additional living expenses (ALE) for residential occupancies or business interruption (BI) losses for commercial or industrial occupancies. In this chapter, only building repair loss calculations are discussed for brevity. This loss considers repair and replacement due to both structural and nonstructural damages, and this is calculated as the product of the probability

of a component in a given damage state and the mean repair costs for that damage state, summed over all the building subsystems and the damage states as given below:

$$L_i = RC_i \cdot \sum_{k=1}^3 \sum_{j=2}^5 P_{ijk} \cdot DR_{ijk} \quad (4)$$

where RC_i is the replacement cost of an entire model building i (e.g., wood frame), P_{ijk} is the probability of model building i and subsystem k (e.g., NSD) being in damage state j (e.g., moderate), and DR_{ijk} is the mean damage ratio for building i and subsystem k in damage state j . The ratio of loss of building L_i and the replacement cost of RC_i is the mean damage ratio (MDR) of the building i for the intensity of GM at which the losses are calculated. This calculation is repeated at different intensities to develop the VF(s) for seismic loss calculations of an individual building or a portfolio of buildings. Note that although HAZUS considers only mean repair cost, simulation-based approach, which will be discussed later on, considers the uncertainty in repair cost as well to calculate the uncertainty in the VFs. Figure 2 shows the VF following HAZUS approach of residential light wood-frame buildings constructed during the period of 1940–1975 following a modern building code (e.g., Uniform Building Code) in the high seismic zone of California for a suite of response spectrum for different magnitude of earthquakes at different distances based on the disaggregation of USGS hazard results in Los Angeles.

Assembly-Based Vulnerability (ABV)/CUREE-Caltech Approach

In this approach (CUREE 2001), the nonlinear building response was calculated based on nonlinear time-history analysis of model buildings representing the best estimate of mass, stiffness (load-deformation characteristics), damping, and building properties required for the analysis. The buildings are modeled as a collection of assemblies of components, such as a gypsum wallboard partition, a floor diaphragm, beams, etc., and each of the assembly is represented by a fragility

function to estimate the probability of that assembly in different damage states as a function of structural response. Test data from the CUREE Project, experimental data from other projects, and observation of damage from different earthquakes are used to develop the fragility functions. The losses were estimated for repair of damage of different assemblies following standard construction cost-estimation principles. This approach estimates mean and uncertainties (which is also improvement over HAZUS) in loss estimate by capturing the uncertainties in: ground motion, structural characteristics, component damageability, and repair costs. This approach followed a simulation approach in order to quantify the (aleatory) uncertainty in the loss results. The losses are calculated for individual components of the buildings instead of a group of components like in HAZUS to get the building loss.

The structural response which is calculated from the building simulation results is used as an input to the fragility function to simulate the damage state of the component assemblies. The components are idealized as an assembly of springs and masses to calculate the response. The masses represent the building components that have significant weight, such as the walls, ceiling, floor, etc., and the springs represent building elements, such as the walls, beams, etc., that resist deformation. The idealization took into account for strength and stiffness degradation of the components, along with many other complex nonlinearities, to represent accurately the spring element. The response parameters used in this approach are maximum interstory drift ratio (IDR), peak floor acceleration (PFA), peak transient horizontal shear strain, peak member forces, and residual drift ratio.

The total repair cost is calculated by summing the cost of repairing the damaged assemblies. The cost of repairing a damaged assembly includes labor costs, material requirements, debris removal, and equipment rental. The cost calculation includes the cost of repair of the undamaged assemblies (or line of sight) due to damage of an assembly. The cost also considers the case of collapse of the building. The cost is simulated from the distribution of the cost for repair of each damaged assembly. The simulation

provides total repair or replacement cost at a given level of seismic shaking intensity. The process is repeated many times at a given intensity to estimate the probability distribution of cost for calculating the building-specific VF. The plot of MDR and coefficient of variation (CoV) of typical wood-frame buildings of average size as a function of PGA based on CUREE-Caltech project is shown in Fig. 2. The plot shows that the prediction of MDR and uncertainty are significantly less than those observed in Northridge earthquake.

PEER-PBEE-Based Approach

Recently, Jayaram et al. (2012) have developed a generic procedure for developing the building VFs by following a systematic simulation approach based on the PEER performance-based

earthquake engineering (PBEE) framework. The steps involved in the procedure are quantifying ground-motion hazard using a *vector of spectral accelerations*; predicting building response parameters such as story drifts, floor accelerations, and residual drifts under the quantified hazard; estimating structural collapse and demolition; and calculating *story-wise losses* based on the responses. The total building loss is calculated by summing the story losses. The procedure captures the effects of epistemic and aleatory uncertainties in different parameters considered in loss calculations, such as ground motions, structural response parameters, loss costs, etc., in order to quantify the uncertainty in the final loss estimate.

The mathematical framework of the development of the mean vulnerability function based on this approach is given below:

$$E(L|S_a(T_0)) = \iiint L \cdot dG(L|DM) || dG(DM|EDP) || dG(EDP|S_a(\mathbf{T})) || dG(S_a(\mathbf{T})|S_a(T_0)) \quad (5)$$

where L is the building loss; $S_a(T_0)$ is the spectral acceleration at a reference period; $E(L|S_a(T_0))$ is the mean loss at $S_a(T_0)$; $dG(L|DM)$ denotes the derivative of the probability of exceedance of the building loss given a damage measure (DM); $dG(DM|EDP)$ is the derivative of the probability of exceedance of the DM given an EDP (e.g., story drift ratio); $dG(EDP|S_a(\mathbf{T}))$ is the derivative of the probability of exceedance of the EDP given a vector of spectral acceleration, $S_a(\mathbf{T})$; and $dG(S_a(\mathbf{T})|S_a(T_0))$ is the derivative of the probability of exceedance of spectral accelerations at multiple periods, $S_a(\mathbf{T})$, given $S_a(T_0)$. Note that the reference period, denoted here T_0 , is not necessarily the fundamental period of the analytical

model of a structure. The fundamental period is a good choice when the structural performance is reasonably elastic and dominated by the first mode, but it is not a good choice for tall buildings in high seismic regions. The response of these buildings is nonlinear when damaged during earthquakes, and the response is determined by multiple frequencies. The equation shows that the structural response is predicted based on a vector of spectral accelerations, but the vulnerability is represented as a function of scalar intensity measure for simplicity of use, but without sacrificing any accuracy.

The variance of the vulnerability function can be estimated as follows:

$$Var(L|S_a(T_0)) = \iiint (L - E(L|S_a(T_0)))^2 dG(L|DM) || dG(DM|EDP) || dG(EDP|S_a(\mathbf{T})) || dG(S_a(\mathbf{T})|S_a(T_0)) \quad (6)$$

The above integrals Eqs. 5 and 6 can be evaluated conveniently by using Monte Carlo Simulation

(MCS). When the number of variables is large, particularly when the intensity measure is of

Seismic Loss Assessment,

Fig. 7 Response spectrum conditioned on $S_a(T_0) = 0.22$ g at $T_0 = 2.5$ s. (a) Exponential of the conditional mean of $\ln S_a(T)$. (b) Conditional standard deviation of $\ln S_a(T)$

large dimension (i.e., vector of S_a), it is efficient and convenient to use MCS. The MCS approach involves simulating all the random variables in Eqs. 5 and 6 (which are $S_a(T)$, EDP , DM , and L) and then computing the mean and the variance of L for a wide range of $S_a(T_0)$ values. The MCS approach provides flexibility and allows consideration of accurate but complex models for different parameters as well as correlation between these parameters. It also allows for the rigorous consideration of collapse and demolition.

Conditional Spectral Accelerations ($S_a(T)|S_a(T_0)$)

Although it is quite common to scale a suite of ground-motion records to $S_a(T_0)$ for nonlinear analysis of buildings for estimating EDPs, studies have shown that this introduces bias in the results – particularly for mid-rise to high-rise buildings (e.g., Haselton 2009). This is due to the fact that the response of these buildings depends on S_a at periods other than T_0 . Hence it

is important to select the records in such a way that the distribution of $S_a(T)$ at all the periods conditioned on $S_a(T_0)$ of the scaled records is appropriate. The mean and variance of a typical conditional spectrum in Los Angeles are shown in Fig. 7. It is observed that variance is zero at the conditioning period T_0 , but the variance increases rapidly as the period of S_a moves further from T_0 . In general, the risk of exceeding $S_a(T_0)$ at a site is caused by earthquakes of several possible combinations of M - R . Since the shape of response spectrum depends on the M - R of earthquakes, there are different possible shapes of response spectrum conditioned on $S_a(T_0)$ due to the different combinations of M - R of earthquakes that can strike a site. The distribution of M - R conditioned on $S_a(T_0)$ at a building site can be obtained by deaggregation of hazard for the site, and this different shaped response spectra should be considered in the simulation of building response to improve accuracy. In the simulation of loss

Seismic Loss Assessment,

Fig. 8 Response spectra for an event ($M_w = 7$ and $R = 10$ km) scaled to the median $S_a(T_0) = 0.12$ g of a set of 98 records and the median spectrum for the set. The median is compared with the average of the four NGA attenuation models (Bozorgnia et al. 2014). The median spectra are closely matched by carefully selecting the set of records

results, first the M and R pairs are sampled based on the distribution from the deaggregation of hazard results, and subsequently, spectral acceleration at multiple periods, $S_a(T)$, conditioned on $S_a(T_0)$, M , and R , is simulated. An example of simulated response spectrum is shown in Fig. 8.

Calculation of EDP

The EDPs required in this approach for loss calculations are interstory drift ratio (SDR), peak floor accelerations (PFA), and residual drift ratio (ResDR). The SDR values are used to predict the damage of SD and NSD components at each story level, the PFA values are used to predict those of the NSA components, and ResDR is used to determine if a building would have to be demolished after an earthquake. The EDPs are first calculated based on nonlinear time-history analysis of buildings for a suite of ground-motion records. But it is nearly impossible to select records that satisfy conditional distribution of S_a at multiple periods (which is can be more than ten for tall buildings) (see, e.g., Jayaram et al. 2012). Hence it is efficient and also accurate to fit regression models to predict independently the different EDPs at different stories and use these fitted models subsequently to estimate the EDPs for the simulated response spectra, which have the right conditional distribution of $S_a(T)$.

Hence the purpose of computing these EDPs by nonlinear time-history analysis for different recorded ground motions is to develop regression models to predict EDPs as functions of $S_a(T)$ while carrying out simulations.

During earthquakes, there is a possibility of collapse of structures. Two different types of structural collapses can be observed during the analysis of buildings. The first type of collapse, *simulated collapse*, is the collapses observed in the analyses. This occurs due to excessive lateral drifts and deterioration that lead to loss of the gravity load resistance of structures. This is modeled using a collapse probability curve, which provides the probability of collapse of buildings as a function of $S_a(T_0)$. The other type is referred to as *virtual collapse*, which captures those cases when a structure in nonlinear analyses undergoes a very large drift without collapse due to limitations in numerical modeling. Both these collapses are considered here for developing vulnerability functions. The collapse probability curve is developed using logistic regression, which is commonly used for regressing binary data (Shome and Cornell 2000), and can be expressed as follows:

$$\ln\left(\frac{p}{1-p}\right) = \beta_0 + \beta_1 \cdot S_a(T_0) + \varepsilon \quad (7)$$

Seismic Loss Assessment,

Fig. 9 Collapse fragility curve for a modern 20-story steel moment-frame building in Los Angeles

where p = probability of collapse, β_0 and β_I = regression coefficients, and ε = regression error. The collapse fragility curve for a 20-story modern steel-frame building is shown in Fig. 9.

In addition to fitting the EDPs at each story for estimating the mean and standard deviation of the loss results conditioned on $S_a(T)$, the correlation between different EDPs at the same story and between EDPs at different stories needs to be estimated to jointly simulate the EDPs. The extent of these correlations is computed using the regression residuals. It is assumed that the EDPs follow multivariate lognormal distribution.

Damage Measure and Repair Cost

In this approach, building component losses are simulated based on the repair costs associated with different damage states, which are obtained from the component fragility functions. Since the damage states are defined to be discrete, the simulation of correlated discrete damage states is a difficult task. It is shown by Shome et al. (2014) that the correlation between discrete damage states can be easily established by representing the fragility functions using a “damage-capacity” formulation. In this approach, instead of defining the correlation between the discrete damage states, the correlation between the damage capacity of different components is defined. The damage capacities of all the components can be jointly simulated from a multivariate lognormal

distribution (the multivariate nature is assumed). The distribution is defined by the means and dispersions of the capacity based on the fragility functions and the correlation between those capacities.

The repair costs conditioned on DM are also modeled as a multivariate lognormal random variable with the median and dispersion and correlations of repair costs between different damage states over the height of buildings. The losses of different components across different damage states are expected to be correlated because of common factors involved in repairs, such as the contractor hired for the repairs and the material costs. The parameters for the distribution of repair cost of buildings are based on the study by Ramirez and Miranda (2009) on the cost of contractors for a large number of building projects. Shome et al. (2014) have shown how the information of repair cost of the contractors can be simulated to estimate the lognormal parameters of repair cost for a specific building or a group of buildings.

The total loss is computed by summing up the sample components losses at each story. This is normalized by the building value to get the damage ratio for the building. The scatter plot of simulation of a 20-story modern steel building in Los Angeles, California, is shown in Fig. 10 as a function of $S_a(T_0)$. The mean and the CoV of the damage ratios are then computed by binning the data points into $S_a(T_0)$ bins to obtain the building VF.

Seismic Loss Assessment,

Seismic Loss Assessment,
Fig. 11 Impact of different sources of epistemic uncertainties in the loss results of a modern 20-story steel moment-frame building in Los Angeles. (a) Average annual loss (AAL). (b) 500-year loss

Seismic Loss Results and Uncertainty in Those Results

The VFs developed in the previous sections are used to carry out seismic risk assessments of buildings. The VFs are integrated with the hazard curves to compute the AAL and the return period or EP losses. As discussed, the methodology

developed by Jayaram et al. (2012) can be used to account for epistemic uncertainties in the vulnerability functions by developing a suite of functions representing the uncertainty. The losses are then sampled from these functions to compute the epistemic uncertainty of different loss matrices used for building risk assessment like AAL, EP loss, etc. Figure 11 illustrates the normalized

64 % confidence interval (CI) of the AAL and the 500-year return period loss of a modern 20-story steel moment-frame building in Los Angeles. The relative extents of contributions of the epistemic uncertainties in vulnerability and hazard to the total epistemic uncertainty would, however, depend on whether the loss assessment is carried out for a single building or a portfolio of buildings. For a single building, as seen in the figure, the VF uncertainty has a large contribution to the total uncertainty. For a portfolio of buildings, however, the uncertainty in losses across different locations will be mostly independent and will average out. The hazard uncertainty, however, is highly correlated across multiple locations and will not average out. Therefore, for a portfolio, hazard uncertainty will have higher contribution to the total uncertainty.

Summary

Seismic loss assessment of buildings plays an important role in managing earthquake risk for public agencies, insurance companies, as well as individual stakeholders. The loss assessment procedure has evolved over the years – from expert opinion to very rigorous analytical approach. Since the analytical procedure is very complex requiring accurate information of a large number of parameters, there is significant uncertainty in accurate estimation of building losses. Hence loss estimation based on observed damage characteristics of buildings in historical earthquakes only can provide accurate loss results. This chapter has discussed in detail the development of building vulnerability functions (VF) based on observed loss data. The data, particularly those that are from insurance companies, can be censored because of insurance deductibles. This is traditionally dealt with maximum likelihood approach and this approach has been described here. But this approach requires a large number of very high-quality building-specific loss data, which is generally not available. The other disadvantage of data-based vulnerability functions is that the

results cannot be extrapolated from one region to the another because of regional building design and construction practices, which are generally unique. Hence this chapter described development of building vulnerability functions based on expert opinion. It is found that this approach can provide significantly biased results and so this is used rarely nowadays. This approach, however, would be used for assessing seismic risk in the future when time and resources are limited.

Over the years, different analytical approaches have been developed and only a few of those have been discussed in this chapter due to limitations in space. This chapter discussed in detail development of vulnerability functions following capacity spectrum method by HAZUS, assembly-based vulnerability, and a comprehensive approach following Jayaram et al. (2012). Analytical approaches have de facto become standard in the recent years for seismic risk calculations. Although these approaches require a large number of parameters, researchers are actively estimating those based on laboratory experiment and observed damage data. It is well known that there is significant uncertainty in the estimation of those parameters vis-à-vis VFs based on those parameters, but the uncertainty in VF can be easily estimated based on the analytical approaches. The importance of consideration of epistemic and aleatory uncertainty and the methodology in order to estimate those in building vulnerability has also been discussed here.

Volcano-seismic monitoring

Introduction

Seismicity beneath a volcano usually increases before an eruption because magma and volcanic gas must first force their way up through fractures and passageways. When magma and volcanic gases or fluids move, they will either cause rocks to break or cracks to vibrate. When rocks break, high-frequency earthquakes are triggered. When cracks vibrate, either low-frequency

earthquakes or a continuous shaking called volcanic tremor, which can last from minutes to days, occurs.

Volcanic earthquakes often occur in swarms, which are clusters in time and space of similar earthquakes without an obvious mainshock. Volcano seismologists look for changes in the rate, size, and location of earthquakes and for the occurrence of swarms and tremor to forecast eruptions and to evaluate whether a volcanic eruption is intensifying or ending. Volcanic hazards including explosive eruptions, rockfall, pyroclastic flows, and lahars also cause ground vibrations and can be identified by their seismic signatures. This makes it possible, in principle, to detect them as they happen and issue warnings.

This entry discusses volcano-seismic monitoring from the viewpoint of a scientist leading a seismic monitoring program at a volcano observatory. Seismic monitoring records continuous, high-sample-rate data on the internal state of the volcano. Other monitoring techniques require manual labor to collect or process data, rely on daylight and good weather conditions, only detect volcanic activity once it has reached the surface, or have a low sample rate. For these reasons, seismic monitoring is the backbone of most volcano observatories. A volcano-seismic monitoring program comprises of a seismic network, a telemetry system, data acquisition, and alarm, analysis, and archival systems. At large observatories, personnel may include electronics engineers, volcano seismologists, seismic analysts, software developers, and network administrators. At small observatories, one person may cover most or all of these roles.

A volcano observatory has to be able to process large quantities of streaming data, detect changes in the volcanic system immediately, and respond without having to do a lot of manual analysis. This requires high levels of automation and systems engineering. While top priority is interpreting real-time data using established knowledge from the scientific field of volcano seismology, other important roles are troubleshooting data problems and conducting (or promoting) research that may lead to a better

understanding of the volcano or lead to improved monitoring tools.

Much of the equipment and software used for volcano-seismic monitoring were originally developed for regional earthquake monitoring. The main difference is that the software needs to be augmented because of the diverse range of seismic signals recorded at volcanoes, many of which elude standard earthquake detection and location techniques. These signals, and the framework in which they are commonly interpreted, are discussed in the next section. The sections that follow describe volcano observatories including the operations room which is the command center during a crisis, the design of volcano-seismic networks, the real-time seismic monitoring and data analysis tools found in most observatories, and the challenges of maintaining this infrastructure and managing data effectively. In the final section, other monitoring techniques employed at observatories are briefly discussed.

Volcano-Seismic Signals

Volcano seismologists are most interested in signals which are anomalous, because they have high amplitudes, characteristic waveforms, or unusual frequency behavior. Given the variety of volcanoes around the world, with staggeringly different eruptive styles, magma compositions, and viscosities, it is perhaps remarkable that some common types of seismic signals are observed. These signals can be broken down into three broad categories: volcanic earthquakes ("events"), continuous signals, and surface signals. Each of these is discussed below. Any volcano may exhibit some or all of these at some time and perhaps may also exhibit exotic signals unique to that volcano. Classification is important because each type of signal may represent a different physical mechanism. However, classification is problematic.

By analyzing the spatial and temporal patterns between different signal types and volcanic activity, a greater understanding of a particular

volcano may be revealed. There are common patterns of behavior, gleaned from analyzing the seismic data from many volcanic eruptions. These are encapsulated in the Generic Volcanic Earthquake Swarm Model (McNutt 1996), a sequence observed at many volcanoes, the main features of which are volcano-tectonic earthquake swarms, followed by low-frequency earthquake swarms, tremor, and eruption.

For a more detailed discussion of volcano-seismic signals and many other topics mentioned in this chapter, Wasserman (2012) is highly recommended.

Volcanic Earthquakes

Volcano-Tectonic Earthquakes

Volcano-tectonic (VT) earthquakes are tectonic earthquakes that occur near active volcanoes. The physical mechanism is shear failure and slip on a fault plane triggered by magma ascent or the relaxation that occurs after magma is erupted. VT earthquakes have clear P- and S-waves (if recorded with a good signal-to-noise ratio) and high-frequency content (>5 Hz). VT earthquakes can be located in the same way as other tectonic earthquakes, i.e., by using the differential travel times between the P and S phases across a seismic network. However, most VT earthquakes are small ($M_L = -0.5$ – 1.5), and poor signal-to-noise ratio often prevents identification of phases, so in practice many (perhaps most) VT earthquakes cannot be located. Velocity models for volcanoes are often poorly determined, making absolute depths unreliable. Trends in relative depths are a useful diagnostic tool, however, and may indicate the rise of magma toward the surface. VT earthquakes frequently occur in swarms that consist of many similar-sized events and do not occur in mainshock-aftershock sequences where one single event dominates.

Long-Period Earthquakes

Long-period (LP) earthquakes are unique to volcanic regions. They have emergent onsets and a narrow frequency range with a peak frequency typically from 1 to 4 Hz. Tornillos are LP

earthquake events with a particularly monotonic appearance and an exponentially decaying tail. LP earthquakes lack discernable P or S phases; consequently, most are not located. Evidence from Soufrière Hills Volcano (Montserrat) that they are often associated with venting from the surface of the dome and often trigger rockfall suggests they may originate at depths of less than 1 km. LP earthquake focal mechanisms reveal a volumetric component which is evidence of a fluid phase. LP earthquake swarms in volcanic systems are often associated with eruptions or intrusions and are believed to be due to processes such as pressure-induced oscillations of fluid-filled cracks in magmatic and hydrothermal systems.

Hybrid Earthquakes

Hybrid earthquakes have a high-frequency P-wave onset, typical of a VT earthquake, followed by a long-period tail. They may represent triggering of an LP earthquake by a VT earthquake. They typically occur in swarms and may be indicative of magma intrusion or extrusion.

Low-Frequency Earthquakes

Collectively, long-period and hybrid earthquakes are referred to as low-frequency earthquakes. There may be a continuum between long-period and hybrid earthquakes.

Deep Long-Period Earthquakes

Some volcanoes produce low-frequency earthquakes (e.g., 20–40 km depth), particularly in the early stages of unrest. These have been called deep long-period (DLP) earthquakes. These have emergent P and S phases, are rich in frequencies below 5 Hz, and are inferred to represent movement of deep-seated magma and associated fluids in the mid-to-lower crust. They look like VT earthquakes with the high frequencies filtered out, perhaps because they occur in a highly attenuating region.

Explosion Quakes and Very-Long-Period Signals

Explosion quakes are signals that accompany Strombolian or other (larger) explosive eruptions.

These signals are identified by the occurrence of an airwave which is caused by expanding gas accelerated at the vent exit. This wave mainly travels through the air with the typical speed of sound (330 m/s at 20 °C).

With the advent of broadband volcanic seismology, very-long-period (VLP) signals have been observed in seismograms from some volcanoes. Many of these are broadband versions of explosion quakes. VLP signals may be produced by the rapid expansion of a large gas volume at shallow depth within the conduit. The gas expansion might result from shallow gas coalescence and expansion or from expansion of a gas slug formed at greater depth.

Continuous Signals

Swarms

Earthquake swarms are sequences of earthquakes closely clustered in space and time without a single mainshock. Volcanic earthquakes often occur in swarms, whereas nonvolcanic earthquakes usually follow a mainshock-aftershock sequence. The Gutenberg-Richter law describes the relative frequency of occurrence of earthquakes of different magnitudes, and this is encapsulated in a parameter called the b-value (see Sanchez et al., “► [Frequency-Magnitude Distribution of Seismicity in Volcanic Regions](#),” this volume). Volcanic earthquake swarms typically have b-values higher than one (most of the energy is in small earthquakes), whereas mainshock-aftershock sequences typically have $b \leq 1$ (most of the energy is in a single mainshock). Volcanic earthquakes occur in hot, highly heterogeneous material containing many small faults. Nonvolcanic earthquakes tend to occur in more homogeneous material with failure on a single larger fault, which then loads adjacent faults, causing many of them to fail producing aftershocks. Low-frequency earthquake swarms often contain one or more families of repeating earthquakes. Each family is identified by a unique waveform and is the result of the same nondestructive source process being activated repeatedly in the same location.

Benoit and McNutt (1996) examined the reports of over 600 swarms to compile the Global Volcanic Earthquake Swarm Database. They identify three main types of volcanic earthquake swarm. Type 1 swarms begin before an eruption and have a mean (and mode) duration of 8 days. Type 2 swarms begin coincident with, or during, an eruption. Type 3 swarms (39 % of records) were not associated with eruptions and have a mean duration of 3.5 days and a mode of 1.5 days. The most common depth for swarms is 2–3 km. Their study does not distinguish between different types of volcanic earthquakes. They suggest it may also be biased by the underreporting of swarms not associated with eruptions.

Tremor

Volcanic tremor is a narrowband (usually 1–4 Hz), continuous vibration thought to be due to sustained subsurface movement of magma or volatiles and is often observed before explosive eruptions. It may last from a few minutes to months in duration. Tremor has similar spectral characteristics as low-frequency earthquakes. Harmonic tremor shows one or many regularly spaced overtones in addition to a fundamental frequency. Sometimes spectral peaks in harmonic tremor glide upward (or downward) in frequency over as little as a few minutes. Eruption tremor, a continuous vibration coincident with explosive eruptions, has a wider frequency range (0.5–10 Hz). Dome collapses, lahars, weather storms, and telemetry problems can all produce signals that could be confused with tremor.

Tremor may be the result of continuous excitation of the source that produces low-frequency earthquakes. The resonance of a fluid-filled conduit is one model for the origin of tremor, as it is for low-frequency earthquakes. Interface waves traveling along the crack or conduit wall can produce overtones, like an organ pipe. Gliding lines could be caused by a change in the sound speed of the fluid (e.g., due to a change in bubble density) or a change in a length of the section of conduit that is resonating (e.g., a change in nucleation depth).

Tremor may also be a superposition of low-frequency earthquakes. There are many observations of low-frequency earthquake swarms merging into volcanic tremor. Modeling has shown that harmonic tremor could appear when overlapping earthquake signals occur at regular time intervals that differ by less than 2 % (Powell and Neuberg 2003). As this regular rate of earthquakes gradually increases (or decreases), gliding spectral lines are produced. In this model, tremor is a low-frequency earthquake swarm.

Surface Signals

Surface signals are those generated by hazardous surface processes such as rockfall, pyroclastic flows, and lahars. Since these processes occur at the surface, they mainly generate surface waves.

Rockfall and Pyroclastic Flow Signals

Actively growing lava domes are highly unstable, and blocks can be observed falling almost continuously, disintegrating into smaller blocks and plumes of hot ash. Most of these rockfalls are small, but many generate detectable seismic signals. If larger parts of the dome collapse, or if there is an explosive component destabilizing the blocks, a pyroclastic flow may be generated. Pyroclastic flows are more energetic, produce vigorously convecting ash clouds, behave more like a fluid (less friction), and are therefore able to travel farther and at higher speeds. There is a continuum from the smallest rockfalls to the largest pyroclastic flows, and they mostly are spawned from the part of the dome that is actively growing. Pyroclastic flows can also be generated by the collapse of an eruption column.

Rockfall signals are emergent, contain a wide range of frequencies (1–10 Hz, peaking 3–4 Hz), and are dominated by surface waves. They have been located by exploiting the amplitude distribution of rockfalls signals across the seismic network. On Soufrière Hills Volcano (Montserrat), some rockfall and many pyroclastic flows have a long-period precursor, and it is possible that this is an explosive degassing signal. At Unzen Volcano (Japan), pyroclastic flow signals are found to comprise three parts. First, a dome collapse is

observed simultaneously with a small LP signal. Second, free-falling blocks impact the slope below (and fragment) simultaneous with a 0.5 Hz signal. Third, the fragmented material generates a rockfall signal.

Dome collapse signals are the superposition of many rockfall events, which may be occurring simultaneously on different flanks of the volcano. Dome collapses may last minutes to hours. From studying dome collapse signals, it is possible to tell how long dome collapses lasted and which phases of the collapse were most energetic. Several major dome collapses at Soufrière Hills Volcano (Montserrat) and Merapi Volcano (Indonesia) have been triggered by intense rainfall.

Lahar Signals

The composition of lahars varies from muddy water to highly erosive, dense mixtures of wet ash, rocks, and boulders that set like concrete. Lahars usually occur during or immediately after heavy rainfall. Barclay et al. (2006) found that about 2 cm per hour of rain falling on unconsolidated materials was sufficient to trigger lahars on Soufrière Hills Volcano (Montserrat). However, hot volcanic material can generate lahars by mixing with crater lakes or with snow and ice on glaciated volcanoes. Volcanic activity may also melt the base of a glacier and cause an outbreak flood that briefly rivals the force of a major river. These are particularly common in Iceland and are known in Icelandic as *jökulhlaups*.

Lahar signals are tremor-like signals that can be distinguished from pyroclastic flow signals by their duration (tens of minutes to hours), higher-frequency content (6–10 Hz, up to 100 Hz in some cases), and slower speeds; they show amplitude peaks on different stations perhaps minutes apart as they travel down valley. To improve the detection of lahar signals, seismic stations, video cameras, and tripwires can be added at various positions adjacent to (or within) the valley.

Difficulties of Event Classification

Classification of volcano-seismic signals is difficult. The signal recorded is a convolution of the source signature, propagation and site effects,

and the instrument response, superimposed on noise which varies spatially and temporally. The source signature may be the result of complex interactions between a multiphase fluid and an unknown geometry of dikes and conduits. Further from the source, the signal-to-noise ratio decreases, and increased scattering and separation between P, S, and surface waves lengthen the signal, making it less clear. Inelastic attenuation may be greatest at shallow depths where poorly consolidated, highly fractured material results in higher frequencies being filtered out. Attenuation may also be significant at depths of 20 km or more, because of high heat flow and partial melt. Similar-looking signals at two different volcanoes, or even at the same volcano, might be caused by different physical mechanisms.

Classification is also subjective. Different seismic analysts may disagree on the classification of a particular event. Discrepancies in classification also appear in published literature: an LP in Lahr et al. (1994) looks similar to a hybrid in Luckett et al. (2007). Classification might artificially separate signals that lie along a continuum. The classification scheme may also evolve during volcanic unrest as a wider variety of signals are recorded. For these reasons it is helpful to reassess the event classes used before interpreting trends in their rates of occurrence or locations.

Terminology also differs. Some of the terms describe the frequency content of the signal and others imply a physical mechanism. VT earthquakes are also called high-frequency events and A-type events. LP earthquakes are also called B-type events. Collectively, long-period and hybrid events are called low-frequency (LF) events, because they are both dominated by low-frequency coda. Low-frequency seismicity includes low-frequency events and volcanic tremor.

Interpreting Volcanic Seismicity

A common pattern of volcanic seismicity is described by the Generic Volcanic Earthquake Swarm Model (McNutt 1996). Background seismicity varies from volcano to volcano and can only be established for a particular volcano through a long-established seismic monitoring

record. The first sign of unrest is often an increase in the rate of VT earthquakes, indicating rock fracture due to changes in stresses caused by rising magma. In some cases it may be the occurrence of DLP earthquakes.

When magma reaches shallower depths, volatiles exsolve, and LP earthquakes are recorded. Volatiles cause a reduction in the acoustic velocity and an increase in the impedance contrast of magma cavities, trapping energy and leading to longer, lower frequency signals. As the volatile content increases, more energy is trapped, and this may lead to LP earthquake events called *tornillos*. Narrowband tremor may be generated by continuous vesiculation as magma rises further or by the boiling of groundwater. If groundwater is heated rapidly, a phreatic explosion may result.

At any time in the sequence, magma rise may stall. This may be the end of the unrest, or it may recommence as more magma is injected at depth adding more heat and volatiles to the system. Tremor due to groundwater boiling may subside as the system dries out, leading to a period of relative quiescence. For basaltic systems, an eruption may then occur without further warning.

For andesitic to rhyolitic systems, hybrid earthquake swarms often occur due to repeated shear failure of viscous magma as it gets close to the surface. Hybrid earthquake swarms are frequently associated with growth of a lava dome. If the events merge into a continuous tremor, harmonic tremor and gliding spectral lines might be observed and are the strongest signs that an explosive eruption may be about to occur. During an explosive eruption, violent ground shaking typically manifests as a broadband tremor signal. Explosion earthquakes may be recorded, identifiable by the shockwave that travels through the air and is coupled back into the ground.

Explosive eruptions are short-lived, and hopefully before they occur, any vulnerable populations will have been evacuated. But extrusive eruptions may last for years or decades, with varying levels of activity, spawning rockfall, pyroclastic flows, and lahars. Monitoring these long-lived eruptions presents challenges of its own, since communities are often in close

proximity. Escalations in activity are often preceded by short sequences of VT earthquakes, low-frequency earthquakes, and tremor, perhaps suggesting a batch of new magma rising toward the surface. However, volcano-seismic data have also been used to track the rate, energy, and location of debris flows and estimate extrusion rates.

An important question to answer once an eruption is underway is when will it stop. The first sign may be the cessation of low-frequency seismicity, indicating that volatiles are no longer present in the system, which may be confirmed with gas flux measurements. More significant may be the occurrence of VT earthquakes at depth with fault-plane solutions consistent with magma withdrawal (Roman et al. 2006). Geodetic data may also indicate deflation of the volcanic edifice.

A more detailed discussion of the interpretation of volcano-seismic data is beyond the scope of this entry. There are several excellent summaries of our evolving understanding of volcano-seismology including Chouet and Matoza (2013), Chouet (2003), and McNutt (2000, 2002, 2005).

Observatories

Volcano observatories vary greatly in their level of sophistication. The simplest observatory may be a hut on the flank of a volcano, with a single seismograph recording on paper on a revolving drum. A modern observatory, however, will have a network of seismic stations with data telemetered to the observatory using a variety of communication systems such as FM radio, satellite, and cellular networks. The observatory may be on the flanks of the volcano, within a few miles of the active vent. Or it may be tens or hundreds of miles away, colocated with a university or a government agency. Many observatories monitor a single volcano, but some monitor several. The Alaska Volcano Observatory has operated seismic networks on as many as 32 volcanoes. The Japan Meteorological Agency monitors 47 volcanoes with real-time seismic data. This poses unique challenges: how to monitor so many

volcanoes in parallel, how to interpret the data without being able to see the volcanoes, how to maintain so many networks, and how to manage all the data.

Participation in a volcanic crisis, is an opportunity to help society and also witness some of nature's most spectacular phenomena. Having the right team is crucial. The leader of a volcano observatory must be experienced in volcano monitoring and be committed to the job. The work can be stressful, the hours long, and hard decisions have to be made in the heat of the moment, e.g., regarding evacuations. Weekly meetings play a vital role at many observatories by pulling the team together, integrating data from many monitoring techniques, identifying technical problems, and prioritizing work. All observatory staff must conduct themselves professionally and have the authority to perform the roles assigned to them. Fostering good communications within the observatory and with the authorities and the public builds trust and enhances public safety.

The backbone of a volcano observatory is the seismic monitoring program, and the heart of the observatory is the operations room. It is from there that seismologists track live data streams, coordinate field teams and warn them of hazardous activity, and alert the authorities (and the public) to escalations in activity. When volcanoes are at background level, the operations room may be unoccupied. Periodic data checks, perhaps coupled with automatic alarm systems, may be enough to keep seismologists abreast of significant changes in seismicity. When unrest begins, periodic checks may become more frequent. At some point the operations room is activated and manned 24 h a day.

These different stages of volcanic activity, from background to unrest to impending eruption, greatly impact the level of seismic monitoring that can be done. At background level, seismologists may be able to conduct research. When a crisis is underway, it will be difficult to do anything more than interpret available real-time data using operational tools that are in place. Part of the job of an observatory seismologist is to engineer the infrastructure of the seismic

monitoring program and operations room to be able to respond effectively during a crisis. This infrastructure includes seismic networks and software systems used to monitor volcanic seismicity. These are the subjects of the next two sections.

Volcano-Seismic Networks

Around 550 volcanoes have erupted in historical times, and about 200 of these are seismically monitored. The best networks tend to be around volcanoes that pose a particularly high threat to large population centers, e.g., Etna and Vesuvius (Italy), Rainier and St. Helens (continental USA), and Kīlauea (Hawaii). Many volcanoes are monitored only by a single station, often as part of a regional network. Nevertheless, by tracking the number and cumulative energy of different types of seismic signals recorded each day on a single station, a volcanic eruption can be anticipated. It may then be possible to rapidly deploy sufficient additional stations to locate earthquakes and forecast where and when an eruption may take place.

The most commonly used seismometers for volcano monitoring are short-period sensors. These have a corner frequency of 0.5–2 Hz and come in single (vertical) and three component varieties. Short-period seismometers are usually deployed with analog telemetry. Both have a dynamic range (the ratio between the largest and smallest amplitudes that can be represented) of only a few thousand. This results in signal amplitudes often being “clipped,” which greatly diminishes the monitoring and research value of the data. Three-component portable broadband seismometers, available since the late 1980s, use a force-feedback circuit and typically have a corner frequency of 30–120 s and a dynamic range of several million, allowing them to record signals on-scale even right up on the volcano summit. They have to be coupled with 24-bit digital telemetry systems, which have a similar dynamic range.

Analog-telemetered data are time stamped at the observatory by a time signal from a GPS clock, but modern field digitizers have an input

for a GPS clock and can time stamp data on site (which is more accurate). On-site data recording enables data to be retrieved or retransmitted later if there is a communication outage. Two-way telemetry allows data packets to be resent automatically if they are not received intact and allows troubleshooting and reconfiguring of stations from the observatory without the expense and delay of a site visit.

While a digital broadband network offers many advantages over an analog short-period network, the equipment is more expensive and power requirements are 2–3 times higher, meaning that additional solar panels and batteries are needed. Broadband sensors also require precise leveling. Many analog networks have been upgraded to digital telemetry to improve dynamic range, and most new networks use digital telemetry, but it is still common to find analog telemetry at volcano observatories.

Designing a volcano-seismic monitoring network is complicated and involves multiple trade-offs. For the same budget a volcano observatory may be able to install a few digitally telemetered broadband stations or many more analog-telemetered short-period stations. The best choice depends on the goal.

For a volcano that is far removed from population centers, the goal might be to detect eruptions so that aviation authorities can be warned of hazardous ash clouds, requiring a minimal level of monitoring. For a densely populated region around a frequently active volcano, or one capable of devastating eruptions, higher quality monitoring is needed to provide as much lead time as possible. The magnitude detection threshold may vary from 2 for a regional network to below 0 for a dense volcano-seismic network. Moran et al. (2008) identified four levels of volcano-seismic monitoring and the number of short-period, broadband, strong motion, and infrasound sensors needed within different radii to make those levels of monitoring achievable. Their findings are summarized in Table 1.

A key consideration for locating earthquakes accurately is to minimize the azimuthal gap. A ring of stations, which encloses most of the volcanic-earthquake epicenters, is ideal with a

Seismic Monitoring of Volcanoes, Table 1 Recommended instrumentation to achieve different levels of volcano-seismic monitoring from Moran et al. (2008)

Level	Goal	Recommendation
1	Minimal monitoring/eruption detection Detect $M > 1.5$ earthquakes; crudely locate $M > 3$ earthquakes	Site a total of five seismic stations within 200 km, including two within 50 km of the volcanic center
2	Limited monitoring/unrest detection Detect $M > 1$ earthquakes; crudely locate $M > 2$ earthquakes; determine event type; detect energetic seismic tremor	Site a total of five seismic stations within 50 km, including two within 10 km of the volcanic center
3	Basic real-time monitoring Detect $M > 0.5$ earthquakes; accurately locate $M > 1$ earthquakes; determine event type; detect seismic tremor; on-scale recording of energetic seismicity on at least one station; detect very-long-period events Detect changes in travel time; detect broad-scale changes in seismic velocity Use fault-plane solutions and b-values to determine generalized stress fields near the volcanic center	Site six to eight seismic stations within 20 km of the volcanic center, including two or three stations with at least one three-component sensor and at least one broadband station, within 5 km
4	Advanced real-time monitoring Detect and accurately locate $M > 0$ earthquakes; determine event type; detect and crudely locate seismic tremor; on-scale recordings of energetic seismicity on multiple stations; detect and crudely locate very-long-period events and other very-low-frequency seismicity Determine detailed source properties of tornillos; construct 3-D velocity models (provided local seismicity is sufficient) Detect explosions and possible infrasonic precursors to explosions at restless and (or) frequently active volcanoes Detect detailed stress-field changes by calculating well-constrained fault-plane solutions and (or) moment tensors, mapping b-values at high spatial resolution, and detecting changes in S-wave-splitting directions over time	Site 12 to 20 seismic stations within 20 km of the volcanic center, including at least six broadband stations, as many as possible within 5 km; at least one strong-motion station; and at least two infrasonic stations (with at least two infrasonic sensors per station) at erupting, restless, and (or) frequently active remote volcanic centers

few stations closer to the volcanic center where they can help detect smaller seismic signals and be used to locate summit events with greater precision and improve depth resolution. For stratovolcanoes, all the earthquakes may be within 1–2 km of the volcanic center, whereas for calderas the seismicity might be diffused over an area 15–20 km in radius. It is useful also to have real-time data from at least one more distant station (which may be part of a regional network) to help constrain the depths of deeper events, and to discriminate more effectively between regional and local volcanic earthquakes. These steps make it possible to locate earthquake reasonably well relative to each other, but how well

they match the true locations of the earthquake will depend on the velocity model and to a lesser degree, on the algorithm used to locate the events. The sophistication of the velocity model may vary from a simple one-dimensional regional model with constant velocity layers to 3-D models determined from seismic tomography.

Site selection depends on the geology, topography, accessibility, and noise. It is preferable to install seismometers in solid bedrock, but volcanoes are typically comprised of layers of ash, flow deposits, and boulders. Repeaters may be required on ridges to rebroadcast signals or boost them if transmitting over tens of kilometers, but represent additional expense and

Seismic Monitoring of Volcanoes, Table 2 Some of the best volcano-seismic monitoring networks. The numbers in parentheses indicate number of borehole instruments. All of these networks surpass level 4 as defined in Table 1 of Moran et al. (2008)

Volcano	Stations within 5 km			Stations within 20 km		
	Broadband	Short period	Total	Broadband	Short period	Total
St. Helens (USA)	2	7	9	2	16 (4)	18 (4)
Soufrière Hills (Montserrat)	7 (1)	0	7 (1)	9 (1)	6 (4)	15 (5)
Piton de la Fournaise (Reunion)	14	6	20	16	17	33
Halemaumau, (Hawaii)	12	5	17	19	14	33
Stromboli (Italy)	18	0	18	18	0	18
Etna (Italy)	?	?	13	?	?	34
Vesuvius (Italy)	?	?	17	?	?	21
Erebus (Antartica)	6	6	12	6	6	12

potential points of failure. Sites that require helicopter access will be expensive to maintain, so often it is better to find sites that can be easily reached with four-wheel-drive vehicles or on foot. Sites should be far from traffic and other human noise and also away from any tall obstacles that may be vibrated by the wind, such as trees, cliffs, and radio towers. Burying sensors a few feet below the surface helps suppress high-frequency wind noise and low-frequency noise due to temperature and pressure variations.

Among the best volcano-seismic networks are those used to monitor Piton de la Fournaise (Reunion), Halemaumau (Hawaii), St. Helens (USA), and Soufrière Hills (Montserrat) volcanoes (Table 2). According to the criteria in Table 1, these are all level four networks. A map of the digital seismic network that has been operational in Montserrat since 2006 is shown in Fig. 1. This utilizes a mixture of Guralp CMG-40T broadband and Mark L4-C short-period seismometers, coupled with Guralp DM24 digitizers and FreeWave Spread Spectrum serial port radios. One of the broadband stations has a CMG-3 T seismometer in a 30-m borehole and less than 4-km from the dome. Four more sites feature a dilatometer and 2-Hz seismometer in 200-m boreholes, coupled with surface GPS. The Piton de la Fournaise network also uses CMG-40T and L4-C seismometers, coupled with Kinometrics Q330 digitizers and a combination of wireless internet and FM radio telemetry.

Real-Time Monitoring

Volcanic activity may escalate suddenly, and the ability to rapidly identify anomalous volcano seismicity is critical. Real-time data visualization systems allow scientists to rapidly assess multiple parameters derived from seismic data such as hypocenters, magnitudes, event rates, spectral variations in tremor, etc. Alarm systems alert scientists to large events and the occurrence of high amplitude tremor and volcanic earthquake swarms. Data-rich websites and remote desktop connections allow scientists to respond rapidly to alarm: This is convenient and enhances safety. The US Geological Survey, through its Earthquake and Volcano Hazards Programs, has played a pivotal role in disseminating free, open-source software to aid in volcano-seismic monitoring. This section describes common techniques and software used to examine continuous seismic data and events in more detail.

Continuous Data

Digital Helicorder Plots
The most basic form of real-time data display is the helical drum recorder (often called “helicorders” or “drums”). A pen etches a trace on a smoked sheet (or draws an ink trace on a blank sheet) of paper wrapped around a cylindrical drum. Helical drum recorders have played a vital role in volcano-seismic monitoring, allowing rapid visualization of seismic amplitudes and event identification of signal types.

Seismic Monitoring of Volcanoes, Fig. 1

The Montserrat seismic network from April 2006 (Modified after Lockett et al. (2007)). Telemetry paths are shown as *lines*. The observatory is marked with MVO. Repeater sites are marked with a *gray circle*. Short-period stations are marked with a *triangle*. Broadband stations are marked with a *star*, except for the borehole broadband, MBLY, marked with a *square*. Not shown are the four 200-m borehole short-period stations, operated by the CALIPSO consortium since 2002

Helicorders were ubiquitous until the 1990s and are still used at many observatories today, but they have numerous drawbacks. They require considerable maintenance and provide limited dynamic range. Adjacent traces often overlap, making them hard to read. The data are not amenable to other forms of analysis, and the sheets require storage space. So there has long been a desire to replace helicorders with a software equivalent. Seismic Waveform Analysis and Real-time Monitor (SWARM) ([http://volcanoes.](http://volcanoes.usgs.gov/software/swarm/index.php)

[usgs.gov/software/swarm/index.php](http://volcanoes.usgs.gov/software/swarm/index.php)) is an excellent solution that allows data to be plotted dynamically: The user can select the time range and the scale; the data can be filtered, and short segments of data can be highlighted and replotted as spectra or spectrograms. Many observatories have now replaced large collections of helicorders with multiple screens showing SWARM displays from different seismic channels. Figure 2 shows 48 h of seismicity at the Soufrière Hills Volcano in June 1997.

Seismic Monitoring of Volcanoes, Fig. 2 Screenshot of the software Swarm, showing a digital helicorder plot from station MBWH channel SHZ for 48 h from June 23, 1997. Remarkable cyclic hybrid swarms are visible.

In June 25, a moderate dome collapse sent pyroclastic flows the northern flanks of the Soufrière Hills Volcano, claiming 19 lives

RSAM Plots

Continuous data are often downsampled to one sample per minute, which makes it easier to identify long-term trends in continuous seismic amplitude. The Real-time Seismic Amplitude Measurement system (Endo and Murray 1991) took the average amplitude of the seismic signal in each 1-min time window, and recorded these data into a file. RSAM data do not discriminate between different types of seismicity.

RSAM data show cyclic seismicity clearly (Fig. 3a). Changes in earthquake activity associated with dome-building episodes (Fig. 3b),

weather, and instrumental difficulties are recognized as distinct patterns in RSAM datasets. RSAM data for dome-building episodes gradually develop into exponential increases that terminate just before the time of magma extrusion. Volcanic earthquakes and rockfall show up as isolated spikes on RSAM plots for seismic stations close to the edifice, but seldom for more distant stations. Weather-related noise shows up as low-level, long-term disturbances on all seismic stations, regardless of distance from the volcano. The RSAM system proved valuable in providing up-to-date information on seismic activity for three Mount St. Helens eruptive

Seismic Monitoring of Volcanoes, Fig. 3 (a)

Plot of RSAM data with one sample per minute for station MBWH channel SHZ from June 22 to 29, 1997. The cyclic hybrid swarms mentioned in Fig. 2 are shown clearly. The spikes represent discrete events, e.g., pyroclastic flows. (b) RSAM plot showing the major dome collapse of the Soufrière Hills Volcano (Montserrat) which occurred on July 29, 2001

episodes from 1985 to 1986 and in numerous eruptions at other volcanoes since. Exponential increases in RSAM data commonly precede explosive eruptions. Inspired by RSAM, many other parameters have been computed on 1-min (or 10-min) timescale. For example, RSEM provides a relative measurement of energy on a 1-min (or 10-min) timescale.

Computing the median (rather than mean) amplitude in each time window provides a measurement of tremor amplitude less biased by events or spikes in the data - but is no longer strictly 'RSAM' data. Corrected for the instrument response and geometrical spreading, and then integrating the data, produces reduced displacement. Since 1996 the Alaska Volcano

Observatory has recorded an instrument corrected seismic amplitude and the peak frequency for each vertical-component seismic channel, on a 10-min timescale.

Spectrograms

Changes in tremor spectra may indicate different flow regimes or changes in source parameters such as geometry, sound speed, or ascent rate (Thompson et al. 2002). Harmonic tremor and gliding spectral lines are frequently followed by eruptions. Spectral monitoring can help differentiate between VT and low-frequency earthquakes, or tremor; wind noise; and electronic noise.

The Alaska Volcano Observatory (AVO) began experimenting with high-resolution spectrograms in 1996. For up to eight stations, a spectrogram is plotted underneath a normalized seismic trace. The time resolution is about 10 s and the frequency resolution 0.1 Hz. Each image file (Fig. 4) displays a 10-min seismic trace and spectrogram for up to eight seismic-data channels. These are ordered in increasing distance from the volcano. The data are instrument corrected and color coded, so that ground motions at one station can be easily compared with those at another station, even at a different volcano.

These web-based spectrograms have been a core AVO monitoring tool since 1998, and a seismologist reviews them twice a day. A convenient web interface (<http://www.aeic.alaska.edu/spectrograms/mosaicMaker.php>) shows mosaics of 10-min spectrogram image files (Fig. 5) and enables 12 h of data from more than 20 volcanoes to be reviewed in just 30–45 min. Similar web-based spectrograms are used for monitoring volcanic seismicity in the Cascades and Hawaii.

Tremor Alarms

Tremor is common precursor to eruptions, and strong tremor frequently accompanies eruptions. Observatory seismologists therefore need to be aware when tremor is being recorded. The earliest widely used volcano-seismic alarm system was part of the RSAM system (Endo and Murray

1991), and this is now incorporated in Earthworm (discussed below). The seismologist can choose which stations to monitor and define an amplitude threshold and a duration for each station. Both must be exceeded to trigger a station. The seismologist also must define the number of stations that must trigger simultaneously to declare an alarm. There is also a mechanism which reduces the false alarms due to regional or teleseismic earthquakes: A far away station can be chosen which prevents an alarm being declared when it exceeds an amplitude threshold. The tremor alarm is typically configured for a moderate amplitude and a duration of several minutes (the RSAM system also included an event alarm, which would typically be configured for high amplitude and duration of a few to tens of seconds).

The RSAM tremor alarm system was used to monitor the Soufrière Hills Volcano (Montserrat) from 1999 to 2003. Figure 6 shows the number of alarms issued over this period.

Events

Real-Time Seismic Event Catalogs

During a volcanic crisis, it is vital to have near-real-time information about the rates, sizes, and locations of seismic events, and for this a real-time event catalog is needed. Providing there are at least four stations, event detection software automates the process of capturing anomalous signals in large volumes of continuous data. Each channel of seismic data is detrended, filtered, and rectified, and a running short-term average (typically 1 to a few seconds) and long-term average (typically a few tens of seconds) are computed. Where the STA (short-term average) to LTA (long-term average) ratio exceeds a threshold, a candidate P or S arrival is declared. Association is the process whereby candidate arrivals' "picks" are grouped together based on similar arrival times and geographic location to declare an event. Location techniques typically use a 3-D grid search to minimize the difference between measured and theoretical travel times, given a particular velocity model. For volcanic earthquakes, it is most common to compute a

Seismic Monitoring of Volcanoes, Fig. 4 Seismic traces and corresponding spectrograms for the vertical components of seven seismic stations near Akutan Volcano, corresponding to 10 min of data on April 22, 2014. A regional earthquake is visible clearly around 20:13

UTC. The hottest colors shown (pink) suggest an S-wave ground velocity of 0.02 mm/s. Near-real-time spectrogram plots like this have been linked to the AVO internal website since 1996. The menu at the top of the screen allows easy navigation to other volcanoes or time periods

duration magnitude due to the prevalence of clipped signals from short-period analog telemetry. For on-scale recordings, local magnitude is often also computed. To visualize catalogs, it is

helpful to view event rate and energy rate plots (Fig. 7) and hypocenter plots (Fig. 8).

There are some caveats with event catalogs. Discrete events are only one aspect of volcanic

Seismic Monitoring of Volcanoes, Fig. 5 A spectrogram mosaic, part of the same application shown in Fig. 4. Three hours of data are shown. Regional earthquakes are

visible at 20:13 (Fig. 4) and 22:15. A calibration signal occurs on the top station (AKV) at 22:03. The apparent data dropouts are due to data latency

seismicity. Signals such as precursory earthquake swarms and tremor episodes, or those generated by explosive eruptions, dome collapses, pyroclastic density currents, and lahars, are of the greatest interest from a hazard perspective. Such signals generally evade standard earthquake-detection schemes based on comparing the short-term and long-term signal averages and are not systematically cataloged. The vast majority of volcano-seismic signals lack identifiable phases and so cannot be located with differential travel-time techniques. Earthquake catalogs therefore present only a narrow view of volcanic seismicity. Many volcano-seismic signals are emergent or long in duration, so STA/LTA detectors break down. Events may be masked by high background signals (e.g., tremor, wind, or electronic noise). Station outages also increase the

magnitude at which earthquakes become detectable. Times when an event catalog suggests there is little seismicity may actually be times of high seismicity. Real-time catalogs also suffer from poorly resolved locations and magnitudes – also a review by an analyst later corrects for these.

Swarm Alarms

Earthquake swarms, like tremor, are a common precursor to volcanic eruptions. A real-time event catalog can be used as the basis for detecting earthquake swarms.

Okmok Volcano (Alaska) erupted ash to a height of 15 km on July 12, 2008, after less than 5 hours of precursory seismicity which included an earthquake swarm. Concerned by this, the Alaska Volcano Observatory developed a swarm alarm system. The system identified the

Seismic Monitoring of Volcanoes, Fig. 6 RSAM event alarms (*top panel*) and tremor alarms (*bottom panel*) issued at Montserrat Volcano Observatory between February 1999 and May 2003. In total there were about 4,000 alarms, an average of almost three alarms per day.

The alarm thresholds configured for each station were raised throughout 2000 and 2001 as activity increased. Event alarms typically corresponded to pyroclastic flows and regional earthquakes, and tremor alarms to dome collapses (i.e., a series of pyroclastic flows)

start and end of five swarms that occurred between February and April 2009, as well as significant escalations in the rate of earthquakes and energy release during those swarms (Thompson and West 2010).

Software

Earthworm (<http://folkworm.ceri.memphis.edu/ew-doc/>), is the most widely used system for earthquake and volcano-seismic monitoring today. It is an open-source, data acquisition, and earthquake detection framework developed by the US Geological Survey. It comprises of modules that communicate via messages on shared memory rings. It is used in the National Earthquake Information Center, tsunami warning centers, and regional seismic networks. Earthworm is in widespread use at volcano observatories

today, in conjunction with other tools that expand its real-time monitoring capabilities. Two reasons for this are that all US volcano observatories use them, and the USGS Volcano Disaster Assistance Program deployed them in many countries at the request of foreign governments.

Earthworm is not the only widely used seismic monitoring systems: Alternatives are SeisComP3 (<https://www.seiscomp3.org/wiki/doc>) and Antelope (<http://www.brrt.com/software.html>). Antelope is an excellent framework for developing new monitoring and research tools, but requires a commercial license except for US higher education institutions. SeisComP3 provides a rich set of graphical user interfaces for global and regional seismic monitoring and is particularly suited for tsunami early warning. However,

Seismic Monitoring of Volcanoes, Fig. 7 Two common ways of examining trends in detected events are (upper panel) event rate (also called ‘counts’- the number of detected events per unit time) plots, and (lower panel)

energy release rate plots (computed from magnitude data). The data shown are from Redoubt volcano, Alaska, from 2009/03/20 to 2009/03/23 and are produced using the GISMO toolbox. Energy units are arbitrary

neither currently has adaptations for volcano-seismic monitoring.

Earthworm, SeisComP3, and Antelope are capable of generating real-time earthquake catalogs within a few minutes of event occurrence, and they work well for regional earthquakes and volcano-tectonic earthquakes. However, other volcano-seismic signals lack clear P- and S-waves required to compute even an approximate location. Fortunately, Earthworm includes another mode of event detection called “subnet triggering,” which determines only an approximate event time, and does not attempt to locate an event. This approach is employed by many volcano observatories. Custom code can be added to monitor these events and trigger other calculations. For example, at the Montserrat Volcano Observatory from 2000 to 2003, real-time measurements of the amplitude, energy, and frequency content of new events were made, and

used to regenerate plots on a private web site used by observatory scientists.

Earthworm has the ability to import data from a wide variety of field instrumentation and data servers and includes a variety of earthquake detection, location, and magnitude algorithms. There are modules which compute RSAM data and create daily helicorder and spectrogram plots. Tremor and swarm alarm systems are now included in Earthworm. Other modules can harvest messages about detected events, arrivals, locations, and magnitudes to create a real-time event catalog, serve up plots of event rates and Google Maps of epicenters, and serve data in QuakeML format.

SWARM can either draw data from a SeedLink server, an Earthworm wave server, or an FDSN (International Federation of Digital Seismograph Networks) web service. Another option is a Winston wave server, which emulates

Seismic Monitoring of Volcanoes, Fig. 8 A common way of presenting 3-D hypocenter data is as a set of 2-D slices through the data. In this plot, generated by VolPlot, a program used for many years at the Alaska Volcano Observatory, earthquake hypocenters from Redoubt Volcano in 2009 are shown. The main panel shows epicenters

in map view, and adjacent panels show depth versus latitude and depth versus longitude. These help scientists identify spatial relationships in hypocenter data. At the bottom, depth versus time is shown, which helps scientists recognize if earthquakes are getting closer to the surface. The size of the symbols indicates magnitude

an Earthworm wave server, but stores data in a MySQL database, providing rapid access and a deep data archive. Winston also provides a web interface that allows plotting of helicorder images and RSAM data (RSAM data are precomputed on import to Winston).

Data Analysis

Some analyses are not performed in real time, because it cannot be fully automated or just because the tools to do it well have not yet been developed; but they nevertheless provide timely information that can affect the way scientists interpret activity.

Analyst-Reviewed Event Catalogs

A real-time event catalog is valuable, but it cannot approach the quality of an analyst-reviewed catalog. A seismic analyst will periodically review the detected events, classify them, and delete false events. They might also pick P and S phases, run software to locate events, and compute magnitudes. Such a catalog is essential for research, but can be difficult to produce in a timely manner as volcanic unrest intensifies and decisions need to be made on timescales of minutes and hours, rather than days. During earthquake swarms (and major aftershock sequences), human analysts may be overwhelmed, increasing latency further just when it matters most.

While Antelope and SeisComP3 include an analyst review capability, Earthworm does not. So it is commonly paired with Seisan (<http://seis.geus.net/software/seisan/seisan.pdf>), which is an excellent free software package for processing and editing event catalogs. Seisan can estimate fault-plane solutions, moment tensors, and b-values too. Seisan includes some adaptations for volcano-seismic analysis: It supports event classes such as VT, LP, hybrid, and rockfall and can generate event-rate plots. Event waveforms are typically examined as spectra as well as time series. However, automated event classification is highly desirable because different real-time processing schemes could then be applied to

different event classes. For example, at the Montserrat Volcano Observatory from 2000 to 2003, rockfall signals were directed into an automated rockfall location system.

Automated techniques for classifying events have been tried at some observatories, but remain rare. Many researchers have had success with frequency-based analysis, artificial neural networks, and hidden Markov chains, but typically for only certain types of events recorded at a particular volcano on a particular station. Neither Earthworm, Antelope, or SeisComP3 currently include an auto-classification module.

Swarm Analysis

While event detection software captures many (perhaps most) volcanic earthquake signals, additional events can be found by using a match filter. This technique is particularly useful for tracking repeating, low-frequency earthquakes, since the emergent onsets of this type of event make them notoriously difficult to trigger using an STA/LTA detector. A known event waveform (or part of it) is cross-correlated against continuous data to find additional events in the same “family.” Each family represents a source which is repeatedly activated in a volume that is small compared to the wavelength of the correlated signal. A number of volcanic processes are thought to be able to generate repeating earthquakes, including repeated resonances of fluid-filled cracks, a propagating crack tip that is driven by intruding magma, or even repeated shear failure within a body of magma. Additional analyses of the earthquake locations and the waveform frequency spectra are needed in order to distinguish between these various models. Double-difference relocation can be used to image the spatial evolution of the swarm more clearly.

A related technique is to cross-correlate waveforms from all events in a catalog against each other, to discover all event families. The MATLAB toolbox “GISMO” includes tools to automate this process. During unrest at Redoubt Volcano in 2009, this was used in near real time to monitor the evolution of swarms (Buurman et al. 2012) (Fig. 9).

Seismic Monitoring of Volcanoes, Fig. 9 Cross-correlation plots for six swarms during the crisis at Redoubt Volcano in 2009 (reproduced from Buurman et al. (2012)). Each pixel represents of pair of waveforms that have been cross-correlated. Color represents the maximum cross-correlation coefficient. Time progresses from

top to bottom and left to right in each panel. The top-left to lower-right diagonal represents the autocorrelation of each waveform. The swarms began on: (a) February 26, (b) March 21, (c) March 27, (d) March 29, (e) April 2, and (f) May 2

Locating Phaseless Seismic Signals

The tremor alarm systems mentioned previously are very simple and they lack the ability to locate tremor. Some observatories have exploited seismic data to track the location of tremor and map debris-flow trajectories, which could help mitigate hazards.

Phaseless signals, once identified (via an STA/LTA algorithm or visual inspection), can be approximately located by exploiting the manner in which seismic wave amplitudes decay with increasing distance from the source, due to geometrical spreading and attenuation (Jolly et al. 2002). Alternatively, they can be located by cross-correlating data to determine travel-time differences and then using traditional differential travel-time techniques to locate the source (assuming the wave type is known). The Waveform Envelope Clustering and Correlation (WECC) system (Wech and Creager 2008) reverses this approach. It continuously locates envelopes of continuous waveform data, and if the location errors are small, it declares an event. Designed to locate the episodic tremor associated with the slow slip, it is now being applied to volcanoes.

Detecting Lahars

Lahar signals may appear as high-frequency tremor signals on a volcano-seismic network, but may be difficult to detect and locate without designing a network for lahar monitoring. High-frequency surface waves attenuate rapidly with increasing distance, so the amplitude of high-frequency signals can be indicative of how close a flow is to a seismometer. More dilute flows are also richer in higher frequencies. An existing volcano-seismic network can be adapted for lahar monitoring by adding stations close to the flow channel at various points, enabling lahar signals to be more easily resolved and crudely located using the times of the peak amplitudes on each station, and also the amplitude distribution across the seismic network. Trip wires can be positioned across the valley at different points and at different heights, and the arrival time and location are

known precisely when the wire is cut. Disadvantages are that trip wires only work once and a dilute flow may leave the wire intact. Sophisticated lahar-monitoring systems have been installed at many volcanoes including Rainier, Merapi, and Nevado del Ruiz.

Imaging Spatial Changes in Volcanic Seismicity

There are many techniques for imaging magma storage regions. A volume devoid of volcano-tectonic earthquakes may indicate a large magma storage body, incapable of shear failure. Seismic tomography can reveal volumes with low P- or S-wave propagation speeds. B-value mapping (see Sanchez et al., “► [Frequency-Magnitude Distribution of Seismicity in Volcanic Regions](#),” this volume) can reveal volumes incapable of sustaining large failures, which are often inferred as being associated with magma. In the region around Uturuncu Volcano (Bolivia), the presence of a sill at around 15–20-km depth has been inferred by an S-wave shadow zone. Roman et al. (2006) found that changes in the orientation of fault-plane solutions could be used (retrospectively) to differentiate between volcano-tectonic earthquakes related to the injection of new magma and post-eruptive relaxation.

Ambient noise tomography is another technique, which can be used to detect velocity changes. In active source seismology, an impulsive source is generated at one location and recorded at another. The resulting seismogram is the Green’s function of the path between the sites. If this were done repeatedly, seismic velocity changes along the travel path could be detected. At a volcano, a drop in velocity could be indicative of increased heat flow, faulting, fluid injection, or expansion of the volcanic edifice. MSNoise (<http://www.msnoise.org/>) is a package which has been developed to automate the computation of Green’s functions between all station pairs on a daily basis, allowing velocity changes as small as 0.1 % to be identified. At Piton de la Fournaise Volcano, the locations of dike injections and eruptive fissures have been inferred.

Detecting Explosions

Cleveland Volcano (Alaska) has been erupting frequently in recent years, generating ash clouds that threaten aviation travelling between North America and Asia, and, without a functioning seismic station within a few tens of kilometers, many of these eruptions were previously missed or only recognized later in satellite images. De Angelis et al. (2012) describe a system which exploits data from a seismic network on Okmok Volcano, operated by the Alaska Volcano Observatory, to detect explosions at Cleveland Volcano (about 120 km away). An STA/LTA detector creates candidate arrivals. For those that fall within a 2-min sliding window, the differential travel times are computed by cross-correlating envelopes of the seismograms and then inverted for apparent slowness. If this is consistent with a sound speed of 340 ± 30 m/s in the direction of Cleveland, an alarm is sent by email. An alternative to the Cleveland explosion alarm mentioned above looks for a coherent signal across an infrasound array instead. The advantage is that infrasound sensors record explosion signals less ambiguously, and the technique could be used to detect explosions in other regions where installation of a local seismic network is unrealistic.

Technical Challenges

One of the major challenges for observatories and seismic networks is monitoring the state of health of a seismic network. There is only one chance to gather data, and in a crisis, data not collected in real-time have little value. Seismic and repeater stations need to be engineered to withstand weather variations which may include heavy rain, snow and ice accumulation, strong winds, and months of little solar energy. Spare equipment needs to be available so that stations can be fixed quickly when a seismic station component breaks. Vandalization by humans, damage by animals, and theft are other considerations. During unrest, ash build-up on solar panels can quickly cause power loss at a seismic station.

Problems will usually be apparent with tools volcano seismologists use every day. RSAM plots may reveal diurnal cycles in the data which may indicate undercharging of batteries or anthropogenic noise. Spectrograms and seismograms may show a flat signal (power loss), a one-sided signal (stuck seismometer), large offset (seismometer not level), white noise (loss of seismic signal), or spikes and dropouts (interference). These can cause havoc with automated detection and alarm systems, leading to corrupted event catalogs and false alarms, so one strategy is to identify and eliminate affected stations from automated processing schemes. SeisNetWatch (<http://www.isti.com/products/seisnetwatch/>) is used by many seismic network operators to monitor all ip-addressible nodes in a network, including field digitizers, to monitor data latency and other state-of-health parameters.

The volume of data flowing into an observatory can be overwhelming. A single channel of 24-bit, three-component data recorded at 100 Hz requires 620 MB of storage per day (uncompressed). Twenty channels of data, a typical amount for a small volcano observatory, are about 1.5 TB per year. Although this would fit on a single hard drive today, it is about 100 times the capacity of a hard drive available 20 years ago (the storage capacity of hard drives increases by a factor of about 10 every decade). Continuous digital volcano-seismic data before the mid 1990s are rare but, remarkably, the Pacific Northwest Seismic Network recently recovered continuous data saved to tape during the 1980 eruption of St. Helens Volcano.

To improve the reliability of data acquisition and processing systems, several measures can be taken. To protect against power failures, all mission-critical computers can be connected to uninterruptible power supplies and configured to automatically reboot and restart critical processes once power is restored. No one wants to arrive at an observatory on a Monday morning and find that the alarm computer suffered a power outage on Friday night and has not been running since, especially if a significant event occurred. Another measure is to run all mission-critical computers in parallel, providing automatic failover or at

least have pre-configured spare computers ready to plug in whenever a primary computer failed. All potential points of failure can be monitored by a diagnostic alarm system. Finally, a daily checklist helps catch any other problems. All of these measures were taken at the Montserrat Volcano Observatory in 2000, leading to an improvement in the data capture rate and public safety.

Once captured, data need to be managed effectively to preserve them for further analysis and research. Given the capacity of modern hard drives, it is now possible to keep many years of data “online.” Copying data to an off-site location is also becoming more common. Many observatories now transmit real-time data to the IRIS Data Management Center, which not only serves as a backup, but outsources the resources needed to disseminate the data more easily to the research community.

Summary

Volcano-seismologists forecast volcanic activity by analyzing the rates, energy release and spatial distribution of different types of characteristic seismic signals recorded in the vicinity of volcanoes. The most commonly identified signals are VT, LP or hybrid earthquakes. Explosive and effusive eruptions can cause rockfalls and pyroclastic flows, which also generate characteristic seismic signals. Volcanic earthquakes frequently occur in swarms. Swarms and tremor are both common precursors to escalations in volcanic activity. While there is still much that is not understood – the origin of LP earthquakes for example - no other technique provides such detailed information about the internal state of a volcano, or about debris flows as they occur, or provides such a detailed chronology of an eruption.

Volcano-seismic monitoring provides high-sample-rate data, 24 hours a day. Short-period seismometers and analog telemetry are gradually being phased out and replaced with modern broadband seismometers and field digitizers. Two-way telemetry allows observatory staff to diagnose and fix problems sometimes without

an expensive field visit or lengthy data outage. Free, community supported software is available for data acquisition, event detection and location (e.g. Earthworm), real-time data visualization (e.g. SWARM), event processing and catalog production (e.g. Seisan), instead of each observatory reinventing the wheel. Archiving data - including continuous waveform data, derived data such as RSAM, event catalogs and station metadata – is a crucial task that has become much easier thanks to the expanding capacity of hard drives, faster internet, and data management centers such as the IRIS DMC.

Real-time monitoring may rely on an operations room which is manned 24 h a day. Or it may rely on automated alarm systems that alert observatory staff to escalations in seismicity (and data outages) outside of normal office hours. Research and development is often driven by the need for better real-time monitoring tools – automated classification of volcano-seismic signals, for example. Ambient noise tomography and detection of multiplets are examples of techniques that might become routine at volcano observatories as computational power continues to increase. As automated monitoring becomes increasingly sophisticated, observatory seismologists will need to spend less time on troubleshooting and development and more time analyzing and interpreting volcanic-seismicity, and collaborating on research.

Introduction

Measuring of ground motion provides the most essential observations made from earthquakes and the basis for research within seismology and earthquake engineering. The measurements are done by seismic stations that are equipped with sophisticated instruments and are placed at specific selected locations. The good quality of these data is obviously important but can only be achieved if many different factors are considered. Often, the approach is adjusted to the scientific or monitoring needs and the available funding. This section deals with systems of seismic stations, so-called seismic networks and data quality-related issues.

Seismic Networks

Seismic networks are systems of individual seismic stations with the purpose to monitor ground motion. The size and configurations of seismic networks depend on the focus area and type of signals that are to be recorded. The data provided by seismic networks (seismograms; see Fig. 3) can be used for many different applications from

earthquake monitoring services to research of the Earth interior. Examples of seismic networks are global seismograph networks (Fig. 1) that are operated to primarily detect large earthquakes and other events globally, regional or national seismic networks to detect events within a country, microseismic arrays to detect induced earthquakes at a water reservoir or hydrocarbon field, and dense monitoring at volcanoes to measure the ongoing activity. Individual seismic stations are commonly part of several networks as sharing of data is common practice. Seismic networks can be either permanent or temporary (e.g., <http://www.usarray.org/>), i.e., deployed for a shorter limited time period often linked to very specific research projects. Normally, less effort is put into the installation of temporary networks.

Seismic Stations

The main elements of a seismic station are the vault and housing of the equipment, the power supply to the equipment, the sensor, the digitizer with a timing device and recorder, and communication. Figure 2 shows how these units can be connected at a seismic station, and Fig. 5 shows

Seismic Network and Data Quality, Fig. 1 Map of the Global Seismograph Network (GSN)

Seismic Network and Data Quality, Fig. 2 Equipment used at a typical seismic station. The analog signal from the sensor is converted to a computer-readable format in the digitizer that also time stamp the data with a GPS; a datalogger is storing and handling the transmission the

data. A router and Internet connection are standard equipment for the data transmission. Some units will have integrated datalogger and digitizer or integrated digitizer and sensor. The units will naturally also need power supply

an example of a seismic station. All these elements will have an effect on the data quality and have to be considered carefully. When building a seismic station, there are normally financial constraints, and one has to find the optimum solution also considering the main monitoring purpose. The main choice for the sensor is between seismometer, also referred to as weak motion sensor, and accelerometer, also called strong motion sensor. The difference is that seismometers are more sensitive, particularly at lower frequencies, and the accelerometer will have a higher clip level than the seismometer. At some seismic stations, both a broadband seismometer and an accelerometer are installed to improve the dynamic range of the seismic station.

The main parameters describing the seismometer are the sensitivity, the natural frequency, and the damping. The response of the seismometer is given by its transfer function (impulse response) that has an amplitude and phase-delay part. Seismometers are available with different natural periods. Traditionally, long-period and short-period sensors were used, where the maximum gain would have been at 20 s and 1 s, respectively. Today, broadband sensors are the most common and typically have the high sensitivity between 120 s and 50 Hz. Seismometers are able to record the lowest possible expected ground noise levels within a given frequency band (limited by the instrument self-noise), and this is the most important technical specification of the

sensor. Accelerometers remain on-scale even for the largest earthquakes and are the most common instrument for earthquake engineering applications.

The main considerations when choosing a digitizer are the dynamic range and the timing accuracy. An important setting on the digitizer is the sampling rate, which according to the Nyquist theorem allows to resolve frequencies less than half the sampling frequency. A normal sampling rate at a local seismic network is 100 Hz. Information of earthquake signals above 50 Hz is therefore not recorded, due to the Nyquist theorem. The sampling rate is thus set according to the expected signal frequencies but also restricted by limitations in data storage and communication. Communication to a seismic station can be achieved in many different ways (e.g., cell phone, satellite, the Internet, digital radios) and is an important element as this allows data to be available close to real time. Most seismic stations are able to send data in this way to one or several central recording systems, and this is what today defines a seismic network.

Before one selects instrumentation for a seismic station, it should be considered if the instrument will be able to properly record the earthquakes it is meant for. A way to verify these requirements is to display the instrument sensitivity and clip levels in frequency–amplitude diagrams, with the expected response of likely earthquakes. Figure 3

Seismic Network and Data Quality, Fig. 3 Frequency–amplitude plot for octave-wide band passes of ground-motion acceleration. The blue polygon represents the sensitivity limits of an STS-2 broadband seismometer, where the frequency limit at 50 Hz is given by the Nyquist frequency for a sample rate of 100 Hz. The lower acceleration amplitude limit in the band 0.001–50 Hz is the minimum sensitivity of the sensor,

and the upper acceleration amplitude limit in the band 0.001–50 Hz is the clip level for the sensor. Sensor limits are scaled down to account for the band passing of the data. The red lines show the possible acceleration levels from different magnitude regional earthquakes that can be recorded at a distance of approximately 100 km. The two black lines show the USGS high- and low-noise models (Peterson 1993) (See also Clinton and Heaton 2002)

shows such a diagram for an STS-2 seismometer with regional earthquakes of magnitudes 1.5, 3.5, 5.5, and 7.5. Note that a magnitude 7.5 is above the clip level in this case, so another type of sensor should be considered for earthquakes of this strength. Figure 4 shows an example of a clipped seismic signal from a regional earthquake.

Data Exchange

The exchange of seismic data has been practiced since the installation of the very first stations as little could be done based on single stations. Prior

to the exchange of digital data through the Internet, seismologists would mail the seismograms on paper or microfilm to each other. Today, it is still common practice (with some exceptions) to exchange and share data between the now enormous number of seismic stations. This sharing of data is essential for research projects as well as for seismic monitoring services as earthquakes often occur in between different networks and only a combination of the networks allows good determination of even the basic earthquake parameters. Data (including waveform data and derived data) can be exchanged in many different ways from email to data downloads from a server and receiving data in near real time. There are a

Seismic Network and Data Quality, Fig. 4 Seismogram showing a magnitude 4.2 earthquake recorded at a distance of 87 km on the GID station in Denmark. The channels represent individual sensors oriented in the vertical, north-south, and east-west directions, given by

the Z, N, and E, respectively. The signal is clipped since the signal exceeded the digitizer clip level. The instrument is the short-period 4.5 Hz GeoSIG GBV-315 (Data are from the Geological Survey of Denmark and Greenland)

number of different public domain proprietary protocols for the near real-time exchange of data between the stations and data centers and also for the exchange between data centers. Most of these allow for data exchange in near real time and the recovery of missing data that may occur due to transmission errors. The public domain SeedLink protocol is one of the most used for real-time data transmission, especially in between data centers (Hanka et al. 2000). The SeedLink protocol transmits data in 512 byte packages, where station, channel, location, or network codes can be requested. The SeedLink protocol ensures that data are not lost in case of disconnected transmissions for shorter periods. This is also common in most commercial software solutions for data transmission in seismic networks. The largest data center receiving and providing seismic waveform data globally in a number of ways is the Incorporated Research Institutions for Seismology (IRIS) Data Management System (DMS) (see <http://www.iris.edu/hq/programs/dms>). It is also becoming possible to operate distributed data centers as, for example, done in Europe through the ORFEUS European Integrated Data Archive (EIDA) initiative (<http://www.orfeus-eu.org/eida/eida.html>). Exchange of parametric data, the data that contain information

on earthquake (e.g., phase travel times and amplitudes), is often carried out between neighboring networks. On a global scale, the main center for the parametric data is the International Seismological Center (ISC) (see <http://www.isc.ac.uk>).

Data Processing

The evaluation or processing of the data recorded by the seismic network normally takes place at the central recording site. Depending on the purpose of a seismic network, different automatic processing routines are applied to the data when it comes in. For most networks, the main focus is on detecting seismic events. This is done by checking the seismic signal and detecting changes from the background noise in the signal at individual stations. The information from a number of stations is combined to detect, locate, and estimate magnitude of the seismic events using the entire network. This is done for networks with different dimensions and monitoring purpose requiring different approaches. The outcome from the automatic processing is normally inspected before dissemination to the public in so-called earthquake early warning systems. This type of warning or information dissemination is

Seismic Network and Data Quality, Fig. 5 Example of a seismic station installed in southern Norway. The vault housing (with the seismometer and digitizer) is constructed from prefabricated concrete rings. (*left*).

Communication and power are available from a nearby hut (*right*). (Photo taken by Ole Meyer, University of Bergen)

an important responsibility of seismic monitoring systems. At a later stage, the data are further processed through manual interactive data processing. For both the automatic and manual data processing, there are a number of public domains as well as commercial software packages. Figure 6 shows phase readings done with the SEISAN software package (<http://seisan.info/>).

Metadata

The meta- or descriptive data are an essential part of the seismic data as without these the data is not complete. Data are identified by a so-called SCNL code (giving stations, component, network, and location) and the timing of the data. The station code represents the locality of the seismic station, the component code reflects the instrumentation, the seismic network code identifies the operator of the station, and the location code allows distinguishing between two instruments of the same type at one station. The metadata associated to the data streams will include information such as the location of the station (latitude, longitude, elevation), the orientation of the sensors (azimuth and dip), the sample rate, and the instrument response.

The main standard for seismic data is the Standard for the Exchange of Earthquake Data

(SEED). One part of SEED refers to the waveform data, known as miniSEED; the other part of SEED, known as the dataless SEED, contains the metadata. The network codes for SEED are organized by the International Federation of Digital Seismograph Networks (FDSN, <http://www.fdsn.org/>). In addition to each component of the seismic data, the complete instrument description makes the data complete. This information makes it possible to convert the output recorded at the seismic station into true ground motion. Incorrect metadata is often the source to failed analysis of earthquake records.

Virtual Seismic Networks

Virtual seismic networks or virtual nets are the type of network where data from seismic stations in different seismic networks are collected and processed as a new “virtual” seismic network. The virtual seismic networks are often seen in regions in between two or more seismic networks where a joint processing of data from the region will improve the detection capabilities. An example of such virtual seismic network is the Greenland Ice Sheet Monitoring Network (<http://www.glisn.info/>), where data from nine different seismic networks are collected and processed jointly to improve the detection capability of glacial

Seismic Network and Data Quality,

Fig. 6 Seismogram displaying an earthquake recorded at a distance of about 50 km. The 9.5 s of data shows the three channels of the seismic station BLS5 in Norway. The channels represent individual sensors oriented in the vertical, north–south, and east–west directions, given by the Z, N, and E, respectively. The P and S phases are seen at 19:22:36.5 and 19:22:42.5, respectively (The data is from the National Norwegian Seismic Network. Data are unfiltered)

earthquakes in Greenland. Other virtual seismic networks collect data after quality or instrument type; see, e.g., the `_REALTIME` and `_STS-1` virtual networks operated by IRIS (<http://www.iris.edu/vnets>). A precondition for such networks to operate is the use of common standards for real-time data transmission as described above.

Seismic Noise and Data Quality

With seismic waveform data, a number of parameters can be used to quantify data quality. The main parameters are ambient noise levels, timing accuracy, and data completeness. The noise levels at a seismic station depend on a number of factors including the true ambient ground noise, the vault construction, and the instrumentation. Increased noise levels at a seismic station result in a lower signal to noise ratio, which means that a seismic station is worse in detecting and observing seismic events.

When talking about “data quality,” the question often is whether it is sufficient or insufficient. This depends on the application of the data. For example, a seismic station may perform well for local earthquake recording, but not provide sufficient data for global earthquake monitoring, if the used instruments are designed only to measure seismic signals above 5 Hz or if the ambient noise level is very high at the lower frequencies. If data quality is sufficient, it means that the collected data provides the information needed to answer the questions asked prior to the collection of the data. On the other hand, if data quality is insufficient, it means that the collected data cannot answer the questions at hand. Data quality is therefore a term used to describe if data is adequate for its intended use. The border between sufficient and insufficient data quality is not sharp since data are often collected to answer multiple questions or since the data quality might change over time during the collection of the data.

Improving data quality is first of all achieved by reducing the noise in the data, both for seismic

Seismic Network and Data Quality, Fig. 7 Ambient noise probability density functions (PDF) of data from the HLID station show how cars, calibrations, and other sources are clearly distinguished from the natural ambient noise (McNamara and Boaz 2005). Auto mass re-center and calibration signals are due to the station operator re-leveling the sensor and checking the amplitudes,

respectively. Body wave and surface wave signals show the total power of all the earthquake records in the period of the PDF. LNM and HNM are the low- and high-noise models, respectively. Note the peak in the noise at about 5 s period; this is due to the ocean-generated noise (See also http://geohazards.cr.usgs.gov/staffweb/mcnamara/PDFweb/Noise_PDFs.html)

stations designed to record local or distant earthquakes. The ambient or microseismic noise has both natural and man-made sources. Typical man-made sources are roads, machinery, airports, railways, etc., and within some constraints it is often possible to stay away from these. The main natural source of seismic noise is ocean waves, and while stations can be deployed at some distance from the coastline, it will not be possible to get away from this noise completely. Wind and atmospheric changes also result in increased noise, and this can mostly be avoided by building better seismic vaults, by putting sensors in pressure-tight enclosures, and also by increasing the depth of installation. The seismic instrumentation, both seismometer and digitizer, also has self-noise, and this can be minimized when choosing the equipment but also during the

installation process. The instruments should always be well grounded to avoid static electricity. Also ambient variations in the magnetic field should be avoided since it can limit the quality (Forbriger et al. 2010).

The most common way to present the microseismic noise at a station is to compute acceleration power density spectra and to display the probability of noise levels over a longer time period on probability density plots (McNamara and Buland 2004; McNamara and Boaz 2005). An example is shown in Fig. 7. This type of plot allows the identification of the different noise sources that act at different frequencies. However, one needs to be aware that the “real” ground noise is only resolved in a specific frequency range depending on the equipment.

The noise at frequencies greater than 2 Hz is related to cultural sources. The local maxima at around 4–8 s and 10–16 s are related to standing waves and waves breaking near the shore, respectively; see Fig. 7. Even more long-period noise is related to atmospheric changes. There can be strong differences at individual sites between day and night related to the changes in cultural activity but also between different seasons. For example, in northern Europe the noise caused by the ocean is much higher during the winter compared to the summer.

Borehole sensors are often used to improve data quality, since borehole sensors are not as affected by noise generated at the surface, as sensors placed at or near the surface. The effect is documented by Carter et al. (1991) stating that 945 m below the surface, noise levels between 15 and 40 Hz are reduced by 10 dB. For periods of between 30 s and 100 s, Hutt et al. (2002) report that the noise reduction is most prominent at the first few tens of meters. The disadvantage of borehole installations with respect to surface installations is that the instruments required are more expensive to buy and install and servicing the sensor is more difficult.

Network Maintenance and Quality Control

Seismic networks require a significant amount of maintenance work and attention to detail. Monitoring of the data quality provides an essential tool in the identification of problems with seismic stations. Being able to identify problems and respond quickly is key to successful operation of seismic networks. Recording of changes to instrumentation is also important.

Data quality can be looked at while the data is coming in, later to evaluate the performance of a network or at the end of a temporary deployment. Seismic networks make use of tools to monitor parameters for quality control. One such system is QUACK (Quality Analysis Control Kit) available at IRIS (<http://www.iris.washington.edu/servlet/quackquery/welcome.do>). QUACK provides information on several parameters such as availability,

data completeness, gaps (lack of data in a time interval), noise levels, and data latency (data arriving late). Most seismic networks record data continuously, and measuring data completeness is an efficient tool to evaluate the overall network performance. Checking for gaps is typically done to identify issues with the communication or equipment.

One parameter that can be checked in near real time is the data latency. An increase in latency will indicate unstable communication. If the latency increases continuously, it will indicate that the connection to the station is lost or worse the recorder, digitizer, or other units at the station are broken. Figure 8 shows an example on latency where the connection to the seismic station was down for a few days. Monitoring of latency will also allow evaluating the quality of communication during regular operation.

It is important that seismometers are installed with correct horizontal orientation so that the north and east components are oriented within the true geographic system. It is also possible to have different orientation, but this needs to be recorded with the station's metadata. The orientation of sensors can be computed retrospectively from the recordings of seismic events. For example, the "LDEO Seismology Project: Waveform Quality Center" measures misorientation by comparing computed to observed polarization of surface waves (<http://www.ldeo.columbia.edu/%7Eekstrom/Projects/WQC.html>). They also attempt to measure changes in gain of seismometers over time from recorded data. To record and possibly avoid changes in gain, regular calibration of the seismic equipment should be part of the network routine operation.

When plotting the noise spectra color scaled over time, one obtains spectrograms that are useful in evaluating the changes of noise. Failure of instrumentation will be seen easily as it will look like an apparent sudden change in noise levels. At the ORFEUS Data Center, PSD plots are generated in yearly intervals showing frequency bands around 0.01, 0.05, 0.5, and 2 Hz (http://www.orfeus-eu.org/data/data_quality.html). An example showing a 1-year PSD from the broadband station SFJD in Greenland is seen in Fig. 9.

Seismic Network and Data Quality, Fig. 8 Latency of data streams from the DBG station in Greenland. The latency is the time between the last sample in the data

record and GMT. The connection to the station was lost on April 18th and regained on the 22nd (This figure is generated at <http://www.iris.edu/servlet/quackquery/>)

Seismic Network and Data Quality,

Fig. 9 Power spectral density (PSD) plot of data from the SFJD station in Greenland, covering the year 2011. The *black, red, green, and blue* lines show the frequencies 0.01 Hz, 0.05 Hz, 0.5 Hz, and 2.0 Hz, respectively (With permission from Dr. Sleeman, ORFEUS. This figure is obtained from <http://www.orfeus-eu.org/>)

Site Selection and Vault Construction

The choice of site, selected to record seismic data, is essential to obtain data with a high

quality. One can install instruments of the highest quality at sites where a high ambient noise level will make the data useless for the purpose they were intended for. Before deciding on a specific

Seismic Network and Data Quality,

Fig. 10 Example of BB vaults from the GEOFON network. (a) Underground bunker vault for remote recording, (b) wide and shallow borehole type, and (c and d) simple bunker construction. Note that b–d allow onsite recording since there is a separate recording room (See also Fig. 7.55 by W. Hanka in NMSOP, Vol.1, Bormann (Ed.), 2002)

site, it is common practice to carry out a site survey where all relevant criteria are considered and noise measurements are done for a few days to identify potential noise sources. If the source of the seismic signal that one wishes to record is known, for example, a small area that is known to be seismically active, one should aim to get as close to the source as possible. One should also aim to have stations installed with the highest azimuthal coverage possible. It is of course important to stay away from the man-made sources of noise mentioned above. Site selection is often dependent on other factors than the ambient noise, such as access to power and communication as well as the physical access to the site. One might therefore not always be able to use the site with the lowest noise level, since it does not meet these requirements.

Constructing good vaults is also very important, and possibilities range from boreholes to

relatively deep substantial vaults to rather shallow and simple installations (Fig. 10). The coupling of the sensor to bedrock is very important in all types of installation. If the budget is not limited, one would attempt to build a pier placed on bedrock several meters below the surface. Around the pier, a room would be constructed that would be isolated from the pier. It is essential to achieve rather stable temperatures and pressure around the sensor. Another room may be placed on top to house the remaining equipment. In a simpler setup, one can use a concrete structure with a smaller diameter that has the sensor at the bottom, a few meters below the surface. Care has to be taken to either drain water away or avoid water ingress completely. Many such designs have been made taking into account local conditions and available materials. The type of vault chosen should also be based on the specifications of the equipment that will be used.

Seismic Network and Data Quality,

Fig. 11 Detection capability of the UK seismograph network. Unit is magnitude on the Richter scale. *Green* triangles are broadband stations, *red* triangles are short-period stations, and *blue* triangles are broadband stations operated by other agencies (<http://www.earthquakes.bgs.ac.uk/>)

Detection Capability

If detection of earthquakes is the main purpose of a seismic network, knowledge on the detection capability of the network is essential when the network is designed and evaluated. The detection capability depends on the level of the background noise, the type of instrumentation, and the configuration of the network. The detection capability is mostly improved by lower background noise in the frequency range of interest, the distribution of stations, and their distance to the area of interest. An example of detection capability is shown in Fig. 11. Here it is assumed that the amplitude threshold for the detections of an earthquake must be twice the background noise level and that the earthquake is recorded on at least four stations (http://www.earthquakes.bgs.ac.uk/monitoring/detection_capability.html).

Synonyms

Ambient noise; Cultural noise; Digitization noise; Instrumental noise; Man-made noise; Microseismic noise; Microseisms; Self-noise; Signal-generated noise

Introduction

Seismic signals are usually transient waveforms radiated from a localized natural or man-made

seismic source. They can be used to locate the source, to analyze source processes, and to study the structure of the medium of wave propagation. In contrast, the term “seismic noise” designates undesired components of ground motion that do not fit in our conceptual model of the signal under investigation. What we identify and treat as noise in seismic studies depends on the available data, on the aim of our study, and on the method of analysis. Accordingly, data treated as noise in one context may be considered as useful signals in other applications. For example, short-period noise (frequency >0.2 Hz) can be used for investigating the potential amplification of earthquake-generated ground motions due to local geological site conditions, also termed *microzonation* (e.g., Parolai 2012), and generally, both short- and long-period noise (frequency < 0.1 Hz) can also be used for tomographic studies of inhomogeneities in the Earth’s crust (e.g., ► [Noise-Based Seismic Imaging and Monitoring of Volcanoes](#)).

According to Bormann and Wielandt (2013), disturbing noise in seismic records in a wider sense may comprise:

- Ambient vibrations due to natural sources (like ocean microseisms, wind, etc.)
- Man-made vibrations (from industry, traffic, etc.)
- Secondary signals resulting from Seismic Wave Propagation in inhomogeneous medium (due to *wave scattering* and therefore also termed *signal-generated noise*)
- Effects of gravity (like Newtonian attraction of atmosphere, horizontal accelerations due to surface tilt)
- Signals resulting from the sensitivity of ► [Broadband Seismometers](#) to ambient conditions (like temperature, air pressure, magnetic field, etc.)
- Signals due to technical imperfections or deterioration of the seismic ► [Passive Seismometers](#) (corrosion, leakage currents, defective semiconductors, etc.)
- Intrinsic ► [Seismometer Self-Noise and Measuring Methods](#) of the Seismic

Instrumentation (like Brownian noise, electronic and quantization noise)

- Artifacts from data processing

However, only the first four items are microseismic noise in a proper sense and elaborated in the following whereas the other ones relate to *seismometry* and *data processing* and are referred to only en passant.

The study of earthquakes or the imaging of the Earth with seismic wave arrivals requires ► [Seismic Event Detection](#) above background noise. Levels of natural ambient noise may vary by 60 dB (i.e., a factor of 1,000 in amplitude) depending on location, season, time of day, and weather conditions. This corresponds to differences in detection thresholds for seismic arrivals by about three magnitude units. Therefore, prior investigation of noise levels at potential recording sites is of utmost importance, as is environmental shielding and proper installation of seismic Sensors so as to reduce the influence of various sources of natural and man-made (cultural) noise (see sections “[Causes and Basic Characteristics of Ambient Noise Observed on Land](#)” to “[Improving the Signal-to-Noise Ratio SNR by Data Processing](#)” below; Trnkoczy et al. 2011; Forbriger 2012).

The essay will brief on:

- Different mathematical representations of noise and signals
- Origins of natural and man-made ambient noise
- Basic features of noise in the wide frequency range of interest for the recording of local micro-earthquakes to normal modes of the Earth ($0.2 \text{ mHz} < f < 100 \text{ Hz}$)
- Influence of filter procedures and the sensor environment on the appearance of signals and noise in seismic records
- Task-dependent procedures for signal-to-noise ratio (SNR) improvement of earthquake and explosion records

More than 98 % of all seismological recordings are made on land, despite the growing

interest in ► [Ocean Bottom Seismometer](#) (OSB) installations in order to improve the global ray path coverage for tomographic studies of the Earth and for regional studies of seismicity and Earth structure in the ocean environment. But OBS deployment, operation, and maintenance are rather expensive and logistically demanding, and the noise conditions on the ocean floor are usually worse than on land (Shinohara et al. 2011; Webb 2002). Therefore, this essay will deal, also because of strict space limitations, only with microseismic noise conditions on land. More details about such noise in both environments as well as on the specifics of seismic signals in different bandwidth ranges and related noise-dependent local and global detection thresholds can be found in Bormann and Wielandt (2013).

With respect to historical aspects of the recording and treatment of microseismic noise, it has to be considered that most of the early twentieth-century seismographs by Wiechert, Mainka, Galizyn, Bosch-Omori, Milne-Shaw, and others were mechanical medium-period broadband sensors of low magnification of the ground motion. Only the more sensitive ones with 100–500 times magnification were already able to record the ever-present ground motions with peak amplitudes around 6 s which constitute the dominating background noise for any seismic measurement with maximum amplitudes in the μ micrometer range (Fig. 1). They were termed microseisms. Such recordings were first reported by Algue in 1900. Wiechert (1904) wrote that these microseisms are caused by ocean waves on coasts. Later it was found that it is necessary to discriminate between: (a) the smaller primary ocean microseisms with periods between 10 and 20 s, typically around $14 \pm 2 \text{ s}$ and (b) the secondary or *double frequency microseism* which is related to the main noise peak around $6 \pm 2 \text{ s}$ (Figs. 1 and 2).

Other types of seismic as well as cultural and instrumental noise became more or less disturbing only when the sensitivity of electromagnetic seismographs, and later of electronically amplified seismographs, was raised so much that they were able to resolve even ground

Seismic Noise, Fig. 1 STS-2 velocity broadband record of the 6 s secondary ocean microseisms at the Black Forest Observatory (BFO), Germany, superposed by high-

frequency waves of a local earthquake of magnitude $M_L = 2.2$ that occurred 32 km away (Figure by courtesy of Thomas Forbriger for NMSOP Chapter 4 © IASPEI)

motion amplitudes in the size range of molecules and atoms (10^{-9} to 10^{-10} m).

Noise conditions at seismic recording sites vary globally in the wide range of periods of seismological interest between some upper and lower level, termed the New High Noise Model (NHNM) and the New Low Noise Model (NLNM) according to Peterson (1993). These noise models are expressed in dB of *power spectral density* (see section “[Nature and Theoretical Representation of Signals and Noise](#)”) of acceleration related to $1 \text{ (m/s}^2\text{)}^2/\text{Hz}$ (Fig. 2). However, the actual noise at any recording site corresponds nowhere in the whole range of periods to either the NHNM or the NLNM. Some sites and seismographs are more affected by long-period tilt-noise at a period above 30 s, and this differently in each record component, while others are mostly disturbed by high-frequency ($f > 1\text{ Hz}$) man-made noise.

According to Fig. 2, variations in noise acceleration power are typically within about

30–80 dB, but they are much larger in velocity power (>130 dB) and displacement power (>250 dB). The latter is much more than the dynamic range of common modern digital seismographs with 24 bit *analog-to-digital converter* (ADC) and a dynamic range of 144 dB. In order to resolve, at good sites, at least the ambient noise with a few bits, even at the NLNM level, and still record without clipping also seismic signals from events in a reasonably large range of magnitudes and epicentral distance, current broadband seismographs used are *velocity sensors* such as the STS-1 and STS-2 ► [Recording Seismic Signals](#). Their dynamic range is given in Fig. 3 with respect to the NLNM when measured in a constant relative frequency bandwidth of 1/3 octave and represented by “average peak” amplitudes (see section “[Approximate Conversion of Power Densities into Recording Amplitudes](#)”). In contrast, classical analog records on paper or film had only a dynamic range of

Seismic Noise,

Fig. 2 Envelope curves of acceleration noise power spectral density P_a (in units of dB relative to $1 \text{ (m/s}^2\text{)}^2/\text{Hz}$) as a function of noise period (according to Peterson 1993). They define the new global high (NHNM) and low noise models (NLNM) which are currently the accepted standard curves for generally expected limits of microseismic noise depending on period. No single station site, however, meets in the whole period range the NLNM or NHNM. However, some exceptional seasonal, diurnal, or local site noise conditions may exceed these limits. Also shown are for the NLNM the related curves calculated for the displacement and velocity power spectral density P_d and P_v in units of dB relative to $1 \text{ (m/s}^2\text{)}^2/\text{Hz}$ and $1 \text{ m}^2/\text{Hz}$ (Modified version of Fig. 2 from P. Bormann 1998 © Springer; with kind permission from Springer Science + Business Media)

some 40 dB. They could cover only a very limited range of noise and record signal amplitudes between about 1 mm and 100 mm. Covering a range of 144 dB instead would correspond to covering an amplitude range between 1 mm and 16 km! However, what the actual usable dynamic range of a seismograph means has been discussed in Sect. 4.2.2 of Bormann and Wielandt (2013).

The reasons for the main types of natural and cultural microseismic noise observed on land and strategies for their avoidance or reduction in seismic records are discussed in the following sections after a brief discussion on the principal difference between seismic signals and noise, their mathematical representation, and the correct way of comparison.

Nature and Theoretical representation of Signals and Noise

Fourier Transformation of Continuous and Sampled Transient Signals

Seismograms contain noise and the desired signals. Sometimes the signal is completely masked by the noise. One of the main tasks in applied seismology is to ensure a good signal-to-noise ratio (SNR) both by selecting recording sites with low ambient noise and by data processing. The success of the latter largely depends on our understanding of the ways in which seismic signals and noise differ. The basic mathematical tool for this purpose is the harmonic or *Fourier analysis*, that is, the decomposition of a signal into sine waves. Depending on the type of signal

Seismic Noise, Fig. 3 A representation of the bandwidth and dynamic range of conventional analog World Wide Standard Seismograph Network (WWSSN) short- and long-period and digital *broadband seismographs* (STS1 and STS2 with good shielding - see Wielandt 2011 and Forbriger 2012) with respect to the equivalent Earth peak acceleration generated by solid Earth tides due to the attraction forces exerted by the Sun and the Moon, by a magnitude 8 earthquake at about 3,300 km distance or by a local earthquake of magnitude 4 at about 10 km distance (see ► Earthquake Magnitude Estimation). The depicted lower bound is determined by the *Instrumental Self-noise*

(also Sect. 4.3.2 in Bormann and Wielandt 2013). The scale is in decibels (dB) relative to $(1 \text{ m/s}^2)^2$. Noise is measured in a constant relative bandwidth of one third octave and represented by “average peak” amplitudes equal to 1.253 times the root-mean-square (RMS) amplitude. NLNM relates to the global New Low Noise Model according to Peterson (1993; see Fig. 2). The requirement to be fulfilled for presenting seismic signal, noise, and clip levels in one diagram has been outlined in Sect. 4.3.3 of Bormann and Wielandt (2013). Copy of Fig. 4.7 in Bormann and Wielandt (2013), compiled by using data of W. Hanka and J. M. Steim; © IASPEI

(transient or stationary, continuous or sampled) different mathematical formulations must be used which have been outlined in detail in Sect. 4.2 of Bormann and Wielandt (2013). The essence is that according to the *Fourier theorem*, any arbitrary *transient function* $f(t)$ in the *time domain* can be represented by an equivalent function $F(\omega)$ in the *frequency domain*. The mathematical relationship between the two domains is defined by the *Fourier integral transformation*:

$$f(t) = (2\pi)^{-1} \int_{-\infty}^{\infty} F(\omega) \exp(i\omega t) d\omega \quad (1)$$

$$F(\omega) = |F(\omega)| \exp(i\phi(\omega)) = \int_{-\infty}^{\infty} f(t) \exp(-i\omega t) dt \quad (2)$$

where ω (in units radian/s) = $2\pi\nu$ is the circular frequency with ν = common frequency

(in units s^{-1}), $|F(\omega)| = \text{amplitude spectrum}$, and $\phi(\omega) = \text{phase spectrum}$. However, the Fourier integral transformation can only be applied to *transient signals* (i.e., signals that disappear or decay after some time so that they have a finite energy). For other signals, the integral may diverge. Moreover, the signals should have been radiated by localized finite sources thus being coherent signals with a defined phase relationship. In the case of digital data, the discrete transformation has to be applied. It also requires a sampled signal of finite duration. In contrast, signals which do not vary much within the interval of time over which earthquake signals are typically analyzed are mathematically treated as *stationary signals*, that is, signals whose statistical properties do not change with time. Such signals require a different mathematical treatment.

Normally, the detailed waveform of stationary signals is of no interest but rather subjected to efforts to remove the disturbing signal from the record. The exception is the above-mentioned application in *microzonation studies* (or *noise tomography*). However, it is of general interest to know how strong such stationary signals are in different parts of the frequency spectrum. This information is contained in a quantity named *power spectral density (PSD)*.

Transient signals such as earthquake seismograms may have a complicated waveform which is determined by the earthquake source, the structure of the Earth, and the properties of the seismograph. The amplitudes and phases of the harmonic components of the signal are not random numbers but follow certain mathematical relationships. Such waveforms or spectra are sometimes called deterministic, in contrast to the “stochastic” or “random” waveform of noise. However, in a strict sense, even microseismic noise is deterministic as well. But the difference is that its sources and propagation paths are not known well enough to predict or interpret the waveform, and therefore it is assumed that the spectral amplitudes and phases are random numbers. Again, this is a mathematical simplification that may or may not be appropriate.

The concept of frequency filtering (e.g., high-, low-, or band-pass filtration) has its roots in analog signal processing and is therefore intimately connected to the *Fourier integral transformation*. Practical computer procedures of the *discrete Fourier transformation*, however, do not use integrals and are often only approximations to the corresponding analog procedures. Supplementary information on different aspects of the Fourier transformation can also be found in Sect. 5.2.3 of Wielandt (2011).

A general problem is that frequency filtering reduces the amplitudes of harmonic components of a signal in part of the frequency spectrum, usually in order to suppress noise. Examples are given in section “[Frequency Filtering](#).” But filtering may also change the waveform of the desired signal in the time domain, the more so the narrower bandwidth. Systematic differences between various magnitude scales as well as magnitude saturation effects are the consequence of filtering the input signals with different responses in different and often rather limited frequency ranges (see ► [Earthquake Magnitude Estimation](#)).

Spectral Analysis of Stationary Signals (Noise)

The analysis of stationary noise usually aims at assessing “how strong” the noise is or whether it will prevent the detection of a specific earthquake signal. Frequency filters may help to suppress noise in one part of the spectrum but still preserve signals in another part. Therefore it is necessary to consider the spectral distribution rather than the total strength of both types of signals. However, the formal measures of “strength” for transient and stationary signals are incompatible and cannot easily be compared. Mathematically speaking, transient signals have a finite energy and zero power (in the average over all times) while stationary signals have an infinite energy but a finite power. The same holds for the spectral densities. For a quantification of stationary noise, the concept of *power spectral density (PSD)* is therefore appropriate while transient signals are more adequately described by their *energy spectral density (ESD)*.

The *Fourier integral transformation* as formulated in Eqs. 1 and 2 has the mathematical property (known as Rayleigh's or Parseval's theorem)

$$\int_{-\infty}^{\infty} f(t)^2 dt = \int_{-\infty}^{\infty} \frac{|F(\omega)|^2}{2\pi} d\omega = \int_{-\infty}^{\infty} |F(2\pi\nu)|^2 d\nu \quad (3)$$

The left side represents, in data processing, the total energy of a signal $f(t)$ which is not the physical energy but proportional to it. The right side represents the energy as an integral of $E = |F(2\pi\nu)|^2$ over all frequencies ν . Thus, according to the above definition, the integrand is the *energy spectral density* E of the signal.

Note that negative frequencies must be included in the integration. For real signals, the ESD is a symmetric function, $E(-2\pi\nu) = E(2\pi\nu)$. Therefore, by multiplying by 2, the integration can be carried out over positive angular frequencies only. This convention is normally used in engineering and other practical applications; the ESD is then given as twice the “mathematical” value. The same applies to the PSD. It is important to clarify which convention is being used.

Power is energy per time, usually expressed as the average power over at least one cycle of an approximately periodic signal. The concept of power is mainly applied to stationary signals such as sine waves or seismic noise whose average power is constant or varies slowly. A Fourier transform in a strict sense is not defined for such signals, but the signal over any finite time interval of length T can be Fourier analyzed. When both sides of Eq. 3 are divided by T , the left side represents the average power, and $P = E/T = |F(2\pi\nu)|^2/T = |F(\omega)|^2/T$ on the right side is then the *power spectral density* $P(\omega)$ for the interval T . But the PSD is not equivalent to a Fourier transform! The signal cannot be reconstructed from it with an inverse transformation because the phase information is lost. The smoothed and decimated PSD is however normally more useful because it contains all essential information in a concentrated form and eliminates arbitrary normalization factors.

The time derivative $\dot{f}(t)$ of a signal $f(t)$ has the Fourier transform $j\omega F(\omega)$. Thus, if the signal was originally measured as a displacement and the Fourier transform of the velocity is of interest then it is obtained by multiplying the original Fourier transform with $j\omega = j \cdot 2\pi\nu$ and the Fourier transform of the acceleration is then $-\omega^2 F(\omega)$. Going back from acceleration or velocity to displacement is achieved by dividing with the appropriate factor. The ESD and PSD are positive quadratic functions of the Fourier amplitudes. Therefore, differentiating the signal brings a factor ω^2 , integration a factor ω^{-2} , etc. A PSD of velocity can thus easily be converted into that of displacement or acceleration.

Representing PSDs in Decibels

As shown in Fig. 2, it has become a standard to measure microseismic noise as a PSD of acceleration, that is, in $(\text{m/s}^2)^2$ per Hz or m^2s^{-3} . But “power” in this context is not the physical power in watts but simply the mean square amplitude of ground acceleration. As in acoustics, the power ratio $r = (a_2/a_1)^2$ between two signals of amplitude a_1 and a_2 is often expressed in decibels (dB). This is a logarithmic measure that expresses a ratio as a difference of logarithms. The difference in dB is $10 \log_{10}[(a_2/a_1)^2] = 20 \log_{10}[a_2/a_1]$. When expressing the power spectral density P_a of acceleration relative to the metric unit $1 (\text{m/s}^2)^2/\text{Hz}$, it holds that

$$\mathbf{P}_a[\text{dB}] = 10 \log_{10} \left[P_a / 1 (\text{m/s}^2)^2 / \text{Hz} \right] \quad (4)$$

In Fig. 2, however, a comparison has been made of the respective numerical values for physically incommensurable quantities such as acceleration power density with velocity and displacement power density. Therefore, Eqs. 2 and 3 and the following two text lines do not imply that the decibel units on both sides of the equal sign mean the same. They only look the same because the incommensurable reference levels were omitted. For this reason, three decibel scales for acceleration power, velocity power, and displacement

power have been given in Fig. 2. This clarification notwithstanding, it holds that numerically

$$\mathbf{P}_v[\text{dB}] = \mathbf{P}_a[\text{dB}] + 20 \log(\omega^{-1}) \quad (5)$$

and

$$\begin{aligned} \mathbf{P}_d[\text{dB}] &= \mathbf{P}_a[\text{dB}] + 40 \log_{10}(\omega^{-1}) \\ &= \mathbf{P}_v[\text{dB}] + 20 \log(\omega^{-1}) \end{aligned} \quad (6)$$

Consequently, for $\omega = 1$ (period $T = 2\pi/\omega = 6.28$ s) it holds that $\mathbf{P}_a = \mathbf{P}_v = \mathbf{P}_d$ (see Fig. 2) although only the numbers are equal! Also, $(\mathbf{P}_d - \mathbf{P}_a) = 2 \times (\mathbf{P}_v - \mathbf{P}_a) = \text{constant}$ for any given period, negative for $T < 2\pi$ s, and positive for $T > 2\pi$ s.

Cross-correlation and Coherence of Seismic Signals and Noise

The *cross-correlation* of two continuous stationary signals $f(t)$ and $g(t)$ at the time lag τ is defined as the expectation value (practically, the mean value) of the sliding dot product $f(t) g(t + \tau)$:

$$(f \star g)(\tau) \stackrel{\text{def}}{=} \int_{-\infty}^{\infty} f^*(t) g(t + \tau) dt, \quad (7)$$

where f^* denotes the complex conjugate of f .

Properly normalized, the cross-correlation is a measure of the similarity between the two signals and is called their *coherence*. Like the power spectral density, it can be calculated via the Fourier transformation and specified as a function of frequency, in which case the name *coherence spectrum* is more adequate. Each signal is fully coherent with itself (*auto-correlation* with the coherence equaling 1). Independent random signals are incoherent (their coherence equals 0) although strictly this is only true in the limit of an infinite duration and after removing the mean. More interesting is the case that signals are partially coherent. Then, with some (frequency-dependent) fraction of the power, a common signal may be hidden in them, for example, a seismic signal masked by instrumental noise of the sensors.

Seismic signals depend not only on time but also on the location where they are recorded. It is

therefore meaningful to ask whether the signal recorded at one location is coherent with the same signal recorded at another location. This aspect of coherence is usually expressed as a “coherence length” over which the recorded signals have a specified coherence. The coherence length is only a fraction of a wavelength for omnidirectional noise (noise propagating in all directions) but can be much longer when noise originates in a limited source area and propagates essentially in one direction towards the station (Fig. 5). In a plane wave, the coherence length is theoretically infinite.

Comparing Spectra and Amplitudes of Transient and Stationary Signals

Bandwidth and Amplitude

Transient signals may be impulsive and oscillatory, and stationary signals either random signals (noise) or monochromatic sine waves. A typical seismogram belongs to the “oscillatory” category. The seismic signal near the focus of an earthquake should be impulsive. Ambient noise is often a superposition of all types, the “random” components being due to a large number of independent sources (traffic, wind, waves in the ocean), “transient” components being caused by identifiable sources such as passing cars, and nearly monochromatic components originating from machinery such as sawmills and pumps.

When the PSD of a stationary signal is constant over the bandwidth of a seismograph or a filter then, when reducing the filter bandwidth, the signal power is proportional to the bandwidth because it is the integral of a constant power density over the bandwidth. The rms amplitude of the signal, which is the square root of the power, must therefore be proportional to the square root of the bandwidth. This explains why a “spectral amplitude density” cannot be generally defined. Such a definition would imply that the amplitude is generally proportional to the bandwidth, which it is not (see Fig. 4.6 in Bormann and Wielandt 2013). It may nevertheless be so in special cases. Consequences of bandwidth differences of seismographs or filter

procedures applied for the evaluation of seismograms have been discussed in detail in Sect. 4.5 of Bormann and Wielandt (2013).

Approximate Conversion of Power Densities into Recording Amplitudes

According to Aki and Richards (1980), the *maximum* amplitude of a wavelet $f(t)$ near $t = 0$ can be *roughly approximated* by the product of what they call the “amplitude spectral density” $|F(\omega)|$ (see Eq. 2) and the bandwidth of the wavelet, i.e.,

$$f(t)_{t=0} = |F(\omega)|2(v_u - v_l) \quad (8)$$

with v_u and v_l being the upper and lower corner frequencies of the band-passed signal. Such an approximation is only possible for signals whose energy is maximally concentrated in time. Likewise, if the power spectral density P of noise is defined as

$$\int_{-\infty}^{\infty} f(t)^2 dt = \int_{-\infty}^{\infty} \frac{|F(\omega)|^2}{2\pi} d\omega = \int_{-\infty}^{\infty} |F(2\pi\nu)|^2 d\nu \quad (9)$$

then the *mean square amplitude* of noise in the time domain is

$$\langle f^2(t) \rangle = 2P(v_u - v_l) \quad (10)$$

This is of course a simplified version of the general rule that the power spectral density (PSD) must be integrated over the passband of a filter to obtain the power (or *mean square amplitude*) at the output of the filter. The square root of this power is then the *root mean square* (RMS) or effective amplitude

$$a_{\text{RMS}} = [2P \times (v_u - v_l)]^{1/2} \quad (11)$$

However, if the power spectral density is defined according to the engineering approach only by its positive frequencies as $P_e = 2P$, then

$$a_{\text{RMS}} = [P_e \times (v_u - v_l)]^{1/2} \quad (12)$$

Stationary signals must be characterized by their PSD, and *specifying noise by its RMS amplitudes is meaningless without definition of the bandwidth*. The values given by the NLNM and NHNM in Fig. 2 follow the engineering power (P_e) convention, and the following related formulas as well.

Often it is necessary to represent the amplitude of noise (whether RMS or average-peak) in a *constant relative bandwidth RBW* over the whole frequency range. This means that the bandwidth B around each frequency ν_0 is a fixed fraction or multiple of ν_0 . The lower and upper band limits, f_l and f_u , are chosen so that f_0 is the geometric mean of the two (i.e., ν_0 appears in the middle between ν_l and ν_u on a logarithmic frequency scale). When the relative bandwidth is n octaves or m decades (n and m normally being fractions, not integers), then the following relationships hold:

$$\begin{aligned} \nu_l &= 2^{-n/2} \nu_0, \quad \nu_u = 2^{n/2} \nu_0, \quad \mathbf{RBW} \\ &= 2^{n/2} - 2^{-n/2} \quad \text{and} \quad B \\ &= (2^{n/2} - 2^{-n/2}) \nu_0 \end{aligned} \quad (13)$$

and (12) can then be written as

$$\begin{aligned} a_{\text{RMS}} &= [P_e \times \nu_0 \times (2^{n/2} - 2^{-n/2})]^{1/2} \\ &= (P_e \times \nu_0 \times \mathbf{RBW})^{1/2} \end{aligned} \quad (14)$$

Octaves can be converted easily into decades and vice versa by using the relation

$$m = n \cdot \log_{10}(2) = n \cdot 0.3010 \quad (15)$$

Typical response curves of short-period narrow-band analog seismographs for recording transient teleseismic body waves (i.e., waves that have travelled more than 2000 km either as longitudinal waves, oscillating in the propagation direction, or transverse waves, oscillating perpendicular to the direction of propagation) typically have bandwidths between 1 to 2 octaves. Different authors have used an integration bandwidth of 1/2 to 1/3 octave (a standard bandwidth in acoustics) for computing RMS amplitudes from PSD. According

Seismic Noise, Fig. 4 Schemes for the generation of (a) primary and (b) secondary microseisms (for explanations see text). L cyclone low-pressure area, X area of interference where standing waves with half the period of ocean waves develop, r distance between L and the coast, Δr

distance between the coast and X , p water pressure, Δp water pressure fluctuation proportional to wave amplitude (Copy of Fig. 12 from Friedrich et al. 1998 © Springer; with kind permission from Springer Science + Business Media)

to the above relationships, 1/3 octave RMS amplitudes will be only about 82 %, 70 %, and 50 % of the respective RMS amplitudes calculated for 1/2, 2/3, or 4/3 octave bandwidth, respectively.

There is a 95 % probability that the instantaneous amplitude of random noise with a Gaussian amplitude distribution will lie within a range of $\pm 2a_{\text{RMS}}$. Peterson (1993) showed that both broadband and long-period noise amplitudes follow closely a Gaussian probability distribution. This is true for largely natural ambient noise, often not, however, for short-period and broadband noise in urban and industrialized areas. There the noise is often dominated by transient or periodic signals (Groos and Ritter 2009 and section “Microseismic Noise in Urban Environments”). Yet, in case of a Gaussian probability distribution, the absolute peak amplitudes of the narrowband filtered signal envelopes should follow a Rayleigh distribution. In the case of an ideal Rayleigh distribution, the theoretical average peak amplitudes (APA) are $1.253 a_{\text{RMS}}$. Therefore, RMS amplitudes in 1/6 decade bandwidth correspond approximately to average peak amplitudes in 1/3 octave bandwidth.

Causes and Basic Characteristics of Ambient Noise Observed on Land

Signals which have a similar waveform and polarization, so that they can interfere

constructively, are termed coherent. This is usually the case for seismic signals generated and radiated by a common source process. The degree of coherence is defined by the ratio between the cross-correlation and the autocorrelation of the time series. The cross-correlation is squared and divided by both autocorrelations to render the result independent of the signal amplitudes. It may vary between 0 and 1. For noise, it shows distinct frequency dependence. Spatial coherence may be rather high for long-period ocean microseisms. Accordingly, the correlation radius, i.e., the longest distance between two seismographs for which the noise recorded in certain spectral ranges is still correlated, increases with the noise period. It may be several kilometers for $f < 1$ Hz but drops to just a few tens of meters or even less for $f > 50$ Hz. For random noise, it is usually not larger than a few wavelengths.

Primary and Secondary Microseisms

Primary ocean microseisms are generated only in shallow waters in coastal regions. Here the wave energy can be converted directly into seismic energy either through vertical pressure variations (Fig. 4a) or by the smashing surf on the shores. Therefore, primary ocean microseisms have the same period as the dominating water waves ($T \approx 10$ to 16 s). Haubrich et al. (1963) compared the spectra of microseisms and of swell at the beaches and could demonstrate a close

relationship between the two data sets. The relative stability in amplitude for continental sites around the globe suggests persistent, stable sources.

Contrary to the primary ocean microseisms, the secondary ocean microseisms could be explained by Longuet-Higgins (1950) and Hasselmann (1963) as being generated by the superposition of ocean waves of equal period traveling in opposite directions, thus generating standing gravity waves of half the period. These standing waves cause nonlinear pressure perturbations that propagate without attenuation to the ocean bottom and there couple into an elastic wave of much larger wavelength and higher phase velocity if the propagation directions are nearly opposite. The area of interference X (Fig. 4b) may be off-shore where the forward propagating waves, generated by a low-pressure area L, superpose with the waves traveling back after being reflected from the coast. But it may also be in the deep ocean when the waves, excited earlier on the front side of the low-pressure zone, interfere later with the waves generated on the back-side of the propagating cyclone. Thus, secondary ocean microseisms are mostly recorded with periods between 5 and 8 s and are the result of energetic ocean waves between the 10 and 16 s period. Horizontal and vertical noise amplitudes of marine microseisms are similar. The particle motion is dominantly of Rayleigh-wave type, i.e., elliptical polarization of the particle motion in the vertical propagation plane. But some energy is present also as body waves, and heterogeneous Earth structure may even couple some energy into Love waves, i.e., surface waves that oscillate parallel to the Earth surface and perpendicular to the direction of propagation with amplitudes that decay exponentially with depth below the surface.

Medium-period ocean/sea microseisms experience low attenuation. They may therefore propagate hundreds of kilometers inland. Since they are generated in relatively localized source areas, they have, when looked at from afar, despite the inherent randomness of the source process, a rather well-developed coherent part, at least in the most energetic and prominent component.

This allows to locate the source areas and track their movement by means of seismic arrays (e.g., Cessaro, 1994; Friedrich et al. 1998, Fig. 5). This possibility has already been used decades ago by some countries, e.g., in India, for tracking approaching monsoons with seismic networks under the auspices of the Indian Meteorological Survey. While near-shore areas may be the source of both primary and secondary microseisms, the pelagic sources of secondary microseisms meander within the synoptic region of peak storm wave activity.

Note that the noise peak of secondary microseisms has a shorter period when generated in shallower inland seas or lakes ($T \approx 2\text{--}4$ s) instead of in deep oceans because of generally shorter wavelengths and periods of the water waves in shallower and smaller water bodies. Also, off-shore interference patterns largely depend on coastal geometries and the latter may allow the development of internal resonance phenomena in bays, fjords, or channels (Fig. 6), which affect the detailed spectrum of microseisms. In fact, certain coastlines may be distinguished by unique “spectral fingerprints” of microseisms.

Long-Period Noise

Ground noise on land observed at frequencies between 0.2 and 50 mHz, i.e., lower than the microseism peak, is usually associated with atmospheric pressure fluctuations. At these frequencies, vertical component seismometers react to changes in gravity as the mass of the atmosphere above a site changes with atmospheric pressure. If seismometers are not fully sealed, they may also experience apparent accelerations due to buoyancy effects on the seismometer mass. Pressure fluctuations may also cause strong longperiod horizontal component noise by distorting the case of the seismometer and/or of the walls of the vault.

Long-period seismometers are also sensitive to temperature changes. Therefore, careful installations aim at sealing the sensor from both pressure and temperature fluctuations (Forbriger 2012). The vertical component noise levels between 0.2 and 1.7 mHz can be reduced by

Seismic Noise, Fig. 5 An example of good spatial coherence of medium-period secondary ocean microseisms at larger distance from the source area which, in this case, allows rather reliable determination of the direction from the station towards the source (backazimut angle = angle measured clockwise from the north) by means of array analysis (see ► Seismometer Arrays). (a) Shows how the

backazimuth determination changed from one day to the next, while (b) shows the location of the two storm areas and of the GRF seismic array. Observations by at least two arrays permit localization and tracking of the noise-generating low-pressure areas (Copy of Fig. 7 from Friedrich et al. 1998 © Springer; with kind permission from Springer Science + Business Media)

more than 10 dB by subtracting the scaled, locally recorded pressure signal from the vertical acceleration record, thereby improving the SNR for normal mode observations (e.g., Fig. 2.23 in

Bormann et al. 2012 and Fig. 4.26 in Bormann and Wielandt 2013).

Turbulence in the atmospheric boundary layer produces pressure fluctuations at the Earth's

Seismic Noise, Fig. 6 Examples for coastline geometries that provide suitable interference conditions for the generation of secondary microseisms (Copy of Fig. 13

from Friedrich et al. 1998 © Springer; with kind permission from Springer Science+Business Media)

surface that cause significant deformation to depths of a few tens of meters below the surface. This noise source is a primary reason why broadband seismometers at permanent stations are often installed beneath the Earth's surface in shallow boreholes (see Sect. 7.4.5 and Fig. 7.59 in Trnkoczy et al. (2011)). For instruments on the surface, short-wavelength atmospheric pressure fluctuations produce a large tilt signal that makes the horizontal components particularly noisy. Tilt couples gravity into the horizontal components but much less into the vertical component (Chap. 5, Sect. 5.3.3 and Figs. 5.8 and 5.9 in Wielandt 2011). The ratio increases with the period and may reach a factor of up to 300 (about 50 dB). Horizontal component local tilt noise may also be caused by traffic and wind pressure.

At very long periods, deformation of the ground, of the seismometer vault, or of the building due to insolation gradients (uneven heating by sunshine) may become noticeable as well. Generally, recording sites poorly coupled to the ground or on poorly consolidated ground will tend to be noisier, both at long and short periods. Other reasons for increased long-period noise may be air circulation in the seismometer vault itself or underneath the sensor cover. Special care in seismometer installation and shielding is therefore required in order to reduce drifts and long-period environmental noise (Wielandt 2011; Trnkoczy et al. 2011; Forbriger 2012).

Short-Period Noise (0.5–50 Hz)

Ambient noise at frequencies higher than those associated with the microseisms peak may have natural causes such as wind (wind friction over rough terrain, trees, and other vegetation or built-up objects swinging or vibrating in the wind), rushing waters (waterfalls or rapids in rivers and creeks), etc. Wind-generated noise is broadband, ranging from about 0.5 Hz up to about 15–60 Hz. But the dominant sources of high-frequency noise are man-made (power plants, factories, rotating or hammering machinery, road and rail traffic, etc.; see Sects. 7.1 and 7.2 in Trnkoczy et al. 2011). Wind-generated noise couples mostly into *surface-wave* modes; cultural noise, however, couples at least partly into *body waves* that can propagate also to greater depth. Cultural noise in records is in principle avoidable, although it is often impractical to place seismic station sites at sufficient distances away from cities or highways. Some rules of thumb suggest that it may be necessary to site short-period recording stations of high magnification as far as 25 km from power plants or rock-crushing machinery, 15 km from railways, 6 km from highways, and 1 km or more from smaller roads. And with respect to moving waters, it is recommended to place stations away from moving water between some 60 km for very large waterfalls and dams to 15 km for smaller rapids (Table 2.1 in Willmore 1979, <http://www.seismo>.

Seismic Noise, Fig. 7 Comparison of the minimum and maximum levels of short-period and long-period ambient noise power observed at stations of the German Regional

Seismic Network (GRSN) (Color version of Fig. 9 from Bormann et al. 1997 © Springer; with kind permission from Springer Science + Business Media)

com/msop/msop79/sta/tab_2.1.gif or Table 7.5 in Trnkoczy et al. 2011). However, noise travels further across competent rock than through alluvial filled valleys. Therefore, “safe” distances may be from 1/2 to 2/3 of the values above, depending on propagation path.

Most of the short-period natural and man-made sources are distributed, stationary, or moving. Their contributions, coming from various directions, superpose to a rather complex, more or less stationary random noise field.

The particle motion of short-period noise is therefore more erratic than for long-period ocean noise and may vary more (by about 30 dB) than long-period noise (by about 10 dB) from station to station within a seismic network. Very pronounced is the seasonal variability of the second-order ocean microseisms by about 30 dB (Fig. 7).

Nevertheless, polarization analysis (the investigation of the different oscillation directions of the various types of seismic waves in space), averaged over moving time-windows, sometimes

reveals preferred azimuths of the main axis of horizontal particle motion, which hints at localized noise sources. Moreover, when the vertical component particle motion in three-component records is clearly developed and averaged, then this indicates the presence of fundamental Rayleigh-wave type polarization. A rather popular and cost-effective microzonation method is based on this assumption. It derives information about the fundamental resonant frequency of the soft-soil cover and estimates local site amplification of ground motion from the peak in the horizontal to vertical component spectral noise ratio (H/V method, e.g., Parolai 2012).

According to the above, every recording site has different noise characteristics depending on its distance from the ocean, industrial and settlement areas, major infrastructure facilities, the wind climate of the site, and the depth of burial of the sensor. At some locations, a seasonal cycle is evident due to variations in wind or water flow in nearby rivers. For example, according to Fyen (1990), spring runoff raises noise levels between 0.5 and 15 Hz at the NORESS array by up to 15 dB. In settlement and industrial areas, a diurnal cycle may dominate due to variable human activity during the day (Fig. 12).

High-frequency noise spectra on land during quiet intervals resemble each other at quieter sites. The rather featureless displacement power spectrum follows a power-law dependence in frequency, proportional to $\approx f^{-2}$ (Fig. 8). This spectral appearance changes drastically due to the strong impact of cultural noise, especially in the frequency band between 1 and 10 Hz (Figs. 13 and 14). Wind noise depends on the strength of the wind and the character of the site. Recorded noise power near 1 Hz in a surface vault may increase by 10–20 dB, as compared to records on calm days, when wind speed reaches about 5 m/s. Short-period wind noise becomes detectable in records at surface sites far from cultural sources at wind velocities above about 3 m/s and at 4 m/s for subsurface sensors as well (Fig. 9). The primary mechanism by which wind couples into high-frequency noise is probably by the direct action of the wind on trees, bushes, and other structures, although at lower frequency the

Seismic Noise, Fig. 8 Displacement power spectral density calculated from 6 moving windows, 50% overlapping, of short-period noise records, 4,096 samples long each, i.e., from a total record length of about 80 s at a rather quiet site in NW Iran (Copy of Fig. 4.6 in Bormann (2002) © IASPEI)

pressure fluctuations associated with wind can directly drive motions of the ground.

Generally, noise levels increase with higher wind speeds. However, there is apparently no linear relationship between wind speed and the amplitude of wind-generated noise. Wind noise increases dramatically at wind speeds greater than 3–4 m/s and may reach down to several hundred meters depth below the surface at wind speeds > 8 m/s (Young et al. 1996). But generally, the level and variability of wind noise is much higher at or near the surface and is reduced significantly with depth (Fig. 9). Moreover, at wind speeds below 3–4 m/s, the background noise may be omnidirectional with relatively large coherence length at frequencies below 15 Hz, but the coherence length is strongly reduced at higher wind speeds with increased air turbulence and local wind pressure fluctuations (Withers et al. 1996).

Comparisons of noise spectra from surface vaults and subsurface installations in mines (Fig. 9) or boreholes (Fig. 10) have repeatedly

Seismic Noise,

Fig. 9 Displacement power noise spectra measured at the surface (*upper curves*) and at 420 m below the surface in a disbanded salt mine at Morsleben, Germany (*lower curves*), on a very quiet day (*hatched lines*) and on a day with light wind on the surface (wind speed about 4 m/s; *full lines*) (Copy of Fig. 4.24 in Bormann (2002) © IASPEI)

Seismic Noise,

Fig. 10 Velocity power density spectra as obtained for noise records at the surface (*top*) and at 300 m depth in a borehole (*below*) near Gorleben, Germany (Figure by courtesy of M. Henger; copy of Fig. 4.23 in Bormann (2002) © IASPEI)

shown significant improvements in SNR for high-frequency phases recorded at depths, sometimes even as shallow as a few meters. Large reductions in noise level may occur already in the first 5 m between the weathered rock of the surface and the more competent rock in the borehole. Note, however, that for periods longer than 2 s the noise reduction is only marginal, even for

sensor deployments at several hundred meters depth.

In case of Fig. 10, the noise power at 300 m depth was reduced, as compared to the surface, by about 10 dB, at $f = 0.5$ Hz, 20 dB at 1 Hz and 35 dB at 10 Hz. The surface-wave nature of ambient noise (including ocean noise) is the reason for the exponential and frequency-dependent

Seismic Noise, Fig. 11 Records of short-period noise (left) and signals (right) at the surface and at different depth levels of a *downhole seismometer array*. Note the significantly larger Pn amplitude closer to the surface. It is

due to the surface amplification effect which may reach a factor of two for vertical incident waves but is less for incidence angles $\gg 0^\circ$ (Fig. copied from Bormann, 1966; modified from Broding et al. 1964)

decay of noise amplitudes with depth. This is not the case for body waves (Fig. 11). Since the penetration depth of surface waves increases with wavelength, high-frequency noise attenuates more rapidly with depth. But both noise reduction and signal behavior with depth depend also on local geological conditions (e.g., section “[Installations in Subsurface Mines, Tunnels, and Boreholes](#)”). Because of the surface-wave character of short- and medium-period noise, the horizontal propagation velocity of ambient microseismic noise depends on frequency. It is close to the shear-wave velocity in the uppermost crustal layers, which is about 2.5–3.5 km/s for outcropping hard rock and about 300–650 m/s for unconsolidated sedimentary cover. This is rather different from the apparent horizontal propagation velocity of P waves and all other steeply emerging teleseismic body-wave onsets.

Broadband spectral levels fall also with increasing borehole depth, but narrow spectral lines due to cultural sources and or waveguide trapping may show less depth dependence. This may result in very different noise decay and signal-to-noise ratio behavior with depth (see section “[Installations in Subsurface Mines, Tunnels, and Boreholes](#)”).

Cultural noise may vary strongly, up to about 30 or even 50 dB at some higher frequencies between sites in different environments (Fig. 14) but also from day to day or with the time of the day at a given site in a busy urban environment (e.g., Fig. 12). Industrial and traffic noise levels are usually lowest on weekends but increase during holidays because of higher traffic. Sources such as power plants, transformer stations, etc. generate narrowband noise, producing energetic spectral lines at 50 or 60 Hz as well as related harmonics and subharmonics (e.g., at 30 Hz, 25 Hz, 12.5 Hz) depending on location (Fig. 13). The NORESS array data included lines at 6, 12, and 17 Hz due to reciprocating saws in a nearby sawmill, and records at Moxa (MOX) station in Germany have been spoiled over decades by a pronounced 2 Hz peak due to a heavy steam engine 16 km away driving a steel-press for rails. It may be possible to remove by frequency filtering such narrowband noise at frequencies that differ from the dominating signal frequency (see section “[Frequency Filtering](#)”). Other types of machinery, however, may also produce narrowband peaks in the noise spectra, but with time-variable frequencies as motor speed may vary. These noise sources are more difficult to remove.

Seismic Noise, Fig. 12 Comparison of relatively quiet sections of vertical component noise records (*left*, without strong transients) and related power spectra (*right*) at a reference site in the district capital town of Miane in NW Iran. The measurements were made at different times of the day (Copy of Fig. 7.15 from Bormann in Trnkoczy et al. (2002) © IASPEI)

Microseismic Noise in Urban Environments

In urban, densely populated, and industrialized environment both natural and cultural noise components may play a major role in a wide range of frequencies. Measuring and analyzing urban seismic noise (USN) requires broadband recordings and data analysis. Figure 14 compares the noise power density spectrum measured at the former seismological station in the city of Hamburg, Germany, with the spectrum measured on a hard rock site in a quiet Spa village some 70 km away, which is now the alternative station site in the GRSN.

From Fig. 14, the following conclusions can be drawn: While in a remote quiet urban setting the microseismic noise spectrum may decay at night almost monotonously towards higher frequencies, the cultural noise activity may increase the daytime PSD for frequencies above 1 Hz by some 10 dB. In contrast, in a very busy

industrialized city such as Hamburg, the microseismic noise level may be 20–40 dB higher for frequencies of about 0.5–30 Hz and may be reduced during night time by less than 10 dB only between 1 Hz and 10 Hz. In the metropolitan city of Berlin, the “cultural noise” patterns differ from that of HAM (see Fig. 7.31 in Trnkoczy et al. 2011) and may again be different in towns with more pronounced diurnal variability of human and industrial activities than in megacities, as in Fig. 12.

Groos and Ritter (2009) stated that the generally high variability of USN does not allow to characterize a sample time series of USN comprehensively by single measures such as the standard deviation of a noise series or the PSD at a given frequency. For the metropolitan city of Bucharest, Romania, they calculated therefore long-term spectrograms of up to 28 days duration from broadband seismic

Seismic Noise, Fig. 13 Noise records and related power spectra near to a transformer house and power line. Note the monochromatic spectral lines around 13, 30, and 50–60 Hz, either induced by the AC current frequency

and its lower harmonics and/or caused by the vibration of the transformer (Copy of Fig. 7.19 from Bormann in Trnkoczy et al. (2002) © IASPEI)

recordings. Spectrograms, or sonograms, are visual 2D representations of the spectrum of frequencies contained in a seismic, sound, or other signal as they vary with time or with some other variable. The aim was to identify the frequency-dependent behavior of the time-variable processes that contribute to USN. Based on the spectral analysis of the data in eight frequency ranges between 8 mHz and 45 Hz, they proposed a time-domain classification which allows to identify both Gaussian distributed noise time series as well as time series that are dominated by transient or periodic signals due to traffic, rotating machinery, etc. In the case of Bucharest, only some 40 % of the analyzed time series are characterized by Gaussian distributed random noise. The most common deviations are due to large-amplitude transient signals. Moreover, significant variations of the statistical noise properties during daytime were found in the wide frequency range between 0.04 and 45 Hz, pointing to a broadband human influence on USN. The authors recommend the use of such automatically derived broadband

information about ambient noise for selecting suitable time windows for H/V noise studies (Parolai 2012) or ambient noise tomography.

Signal and SNR Variations due to Local Site Conditions

Compared to hard rock sites, both noise and signals may be amplified when recorded on soft soil cover. This signal amplification may partly or even fully outweigh the higher noise observed on such sites. Signal strength observed for a given event may vary strongly (up to a factor of about 10–30) within a given array or station network, even if its aperture is much smaller than the epicentral distance to the event (<10–20%), so that differences in backazimuth and amplitude-distance relationship are negligible (Figure 15 and Fig. 4.36 in Bormann and Wielandt 2013). Also, while one station of a network may record events rather weakly from a certain source area, the same station may do as well as other stations

Seismic Noise, Fig. 14 Noise power spectra at HAM (upper two curves, red) and BSEG (lower two curves, blue) determined from vertical-component records at day-time and nighttime. Note that the noise reduction is almost negligible for periods longer than 2 s. The drastic reduction at higher frequencies has been achieved both by the reduced cultural noise sources at Bad Segeberg, as compared to the big city of Hamburg, and by installation of the broadband seismograph in an outcropping local hardrock

salt-anhydrite diapir with very high contrast of its *acoustic impedance* (= product of wave velocity in the medium times density of the medium) against that of the surrounding alluvial softrock layers. This prevents much of the short-wavelength noise energy to penetrate into this local hard rock anomaly (Color version of Fig. 18 from Bormann et al. 1997 © Springer; with kind permission from Springer Science + Business Media)

(or even better) for events from another region, azimuth, or distance (e.g., station GWS in Fig. 16 left and right, respectively).

Figure 16 compares, for regional and teleseismic events, the short-period P-wave amplitude ratio (left) and SNR (right) of two stations of the German Regional Seismic Network (GRSN). In the same azimuth range, but at different epicentral distances, station BRG may record both > 3 times larger as well as > 3 times smaller amplitudes than station MOX. This corresponds to differences in station magnitude up to one unit! The same applies to the differences in SNR. Therefore, optimal site selection cannot be made only on the basis of noise measurements. Also, the signal conditions at possible alternative sites should be compared.

However, differences in local SNR conditions may become negligible in long-period recordings (Fig. 4.39 in Bormann and Wielandt 2013) and thus play a lesser role in site selection for broadband records. Thermal shielding and reduction of

tilt noise then have the highest priority (see Forbriger 2012).

Installations in Subsurface Mines, Tunnels, and Boreholes

As shown in Figs 13–15, short-period microseismic noise is strongly reduced with the depth of sensor installations in mines and boreholes. Withers et al. (1996) found that for rather high frequencies monitoring, as in very local weak motion and industrial seismology measurements between 10 and 20 Hz, the SNR could be improved between 10 and 20 dB and for frequencies between 23 and 55 Hz as much as 20–40 dB by deploying a short-period sensor at only 43 m below the surface. However, depending on geological conditions and related peculiarities of the local noise field as well as the decreasing free-surface amplification effect of incident body waves, the SNR does not necessarily increase steadily with depth. A striking example have been short-period signal and noise measurements

Seismic Noise, Fig. 15 Short-period records of underground nuclear explosions at the test sites of Semipalatinsk (*left*, $D \approx 41^\circ \pm 1^\circ$) and Nevada (*right*, $D \approx 81^\circ \pm 1^\circ$) at stations of the former East German seismic network. Note

the differences in signal amplitudes both amongst the stations for a given event and for the same station, when comparing events in different backazimuth and distance (Copy of Fig. 4.35 in Bormann (2002) © IASPEI)

Seismic Noise, Fig. 16 Pattern of the relative short-period P-wave amplitudes (*left*) and of the related SNR (*right*) at station BRG normalized to those of station MOX

(170 km apart) in a distance-azimuth polar diagram (Modified version of Fig. 7 from Bormann et al. 1992 © Elsevier; with permission from Elsevier)

in the early 1960s with 1 Hz borehole seismometers in two abounded deep oil drills in the USA (Douze, 1964). In the Texas hole, the average ratio of seismic signal in the borehole to that measured at the surface decreased to 1/10th at about 1,500 m depth and then increased again to ½ of the surface value at 3,000 m depth. In contrast, in an Oklahoma borehole, it dropped to about 1/3 at about 1,000 m depth and then remained roughly constant thereafter. Accordingly, despite the noise reduction with depth, there was no SNR improvement (on average) in the Texas borehole down to about 1,000 m depth, but then the SNR increased to a factor of about 15 at 3,000 m depth. Contrary to this, the SNR increased by a factor of 3 in the Oklahoma borehole within the first 800 m but then remained roughly constant (ranging between 1 and 5) up to 3,000 m depth (see Fig. 4.40 in Bormann and Wielandt 2013).

Nevertheless, generally a significant SNR improvement is to be expected within the first few hundred meters depth. This applies particularly to borehole installations of long-period and broadband sensors which benefit already at much shallower depth greatly from the very stable temperature conditions and strongly reduced atmospheric pressure fluctuations and related tilt noise, also in hard rock tunnels. In mines or boreholes, a depth of 100 m below surface is generally sufficient to achieve most of the practicable reduction by -20 to -30 dB of long-

period noise with periods between 30 s and 1,000 s (see Fig. 7.59 in Sect. 7.4.5 of Trnkoczy et al. 2011). Since the cost of drilling and installation increases greatly with depth, no permanent seismic borehole installations deeper than 100–150 m have yet been made. In any event, the borehole should be drilled through the soil or cover of weathered rock and penetrate well into the compacted underlying rock formations. For more information about tunnel and long-period borehole installations, see Sects. 7.4.3 and 7.3.5 in Trnkoczy et al. 2011.

Thus, differences in the frequency spectrum, horizontal wave-propagation velocity, degree of coherence, and depth dependence between (short- and medium-period) microseismic noise and seismic waves allows to improve the signal-to-noise-ratio (SNR) by installing seismic sensors either at reasonable depth below the surface or by way of data processing.

Improving the Signal-to-Noise Ratio by Data Processing

Frequency Filtering

If the dominating frequency content of the seismic signal differs from that of the disturbing noise, then band-pass, high-pass, or low-pass filtering may significantly improve the SNR (Figs. 17 and 18).

Seismic Noise, Fig. 17 *Top:* Velocity broadband record in the period range between 0.5 and 360 s of a teleseismic earthquake. Only the P-phase might be identified. *Bottom:* On the long-period band-pass filtered trace the signal-to-

noise ratio is much improved and several later phases are clearly recognizable (Figure by courtesy of J. Havskov for NMSOP editions © IASPEI)

Seismic Noise, Fig. 18 Isolation of a local $ML = 2.2$ earthquake (*bottom trace*) that occurred 32 km away from the Black Forest Observatory (BFO), Germany, by 2-Hz high-pass filtering of the raw data of a velocity broadband

STS-2 record (*top trace*), thus eliminating the dominating 6 s ocean microseisms (Figure by courtesy of Thomas Forbriger for NMSOP Chapter 4 © IASPEI)

Velocity Filtering and Beamforming

Often the dominant signal frequencies may coincide with that of strong noise. Then frequency filtering does not help to improve the SNR. On the other hand, the horizontal propagation

velocity of noise, being dominantly surface waves of Rayleigh-wave type, is much lower than that of P waves and also lower than that of teleseismic S waves with a steep angle of incidence. Then frequency-wavenumber (f-k)

Seismic Noise, Fig. 19 Detection of a weak underground nuclear explosion in the 10 kt range at the Mururoa Atoll test site ($D = 145^\circ$) by beam forming (*top trace*). No signal is recognizable in any of the 13 individual record traces from stations of the Gräfenberg array, Germany (*below*) (From Buttke 1986 © Schweizerbart <http://www.schweizerbart.de/>)

filtering is suitable to improve the SNR in the beam trace of seismic array records (Schweitzer et al. 2011). Assuming that the noise within the array is random while the signal is coherent, even a simple direct summation of the n sensor outputs would already produce some modest SNR improvement. When the direction and velocity of travel of a signal through an array is known, it is possible to compensate for the differences in arrival time at the individual sensors and then sum up all the n record traces (beam forming). This increases the signal amplitude by a factor n while the random noise amplitudes increase in the beam trace only by $\sqrt{n}$, thus improving the SNR by $\sqrt{n}$. Figure 19 compares the (normalized) individual records of 13 stations of the Gräfenberg array, Germany, with the beam

trace. A weak underground nuclear explosion at a distance of 143.6° , not recognizable in any of the single traces, is very evident in the beam trace.

Noise Prediction Error, Polarization, and Other Multi-parameter Methods of Filtering

In near real time, it is possible to use a moving time-window to determine the characteristics of a given noise field by means of cross- and autocorrelation of array sensor outputs. This allows the prediction of the expected random noise in a subsequent time interval. Subtracting the predicted noise time series from the actual record results in a much reduced noise level. Weak seismic signals, originally buried in the noise but not predicted by the noise “forecast” of the prediction-error filter (NPEF), may then stand out clearly. NPEFs have several advantages as compared to frequency filtering:

- No assumptions on the frequency spectrum of noise are required since actual noise properties are determined by the correlation of array sensor outputs.
- While frequency differences between signal and noise are lost in narrowband filtering, they are largely preserved in the case of the NPEF. This may aid signal identification and onset-time picking.
- Signal first-motion polarity is preserved in the NPEF whereas it is no longer certain after narrow-band or zero-phase band-pass filtering.

Three-component recordings allow to reconstruct the ground particle motion and to determine its polarization which may differ between different types of seismic waves and noise. One great advantage of polarization filtering is that it is independent of differences in the frequency and velocity spectrum of signal and noise and thus can be applied in concert with other procedures for SNR improvement.

Early examples of NPEF and polarization filtering have been given in Bormann and Wieland (2013). For a briefing on modern three-component broadband procedures of SNR

improvement, signal detection, phase identification, and event location that have been implemented in procedures for fully automatic near real-time multi-parameter signal analysis, see Sect. 11.9 in Bormann et al. (2014). These procedures apply cross-correlation methods, use differences in the complexity and polarization properties between signal and noise as well as a compressed signal representation by a sequence of n-dimensional feature vectors which increase the robustness of the procedures. Some of these versions also adapt the signal detector to temporal/seasonal variations in the nature and power of ambient noise.

Summary

The essay defines the term of “seismic noise” and explains why coherent seismic signals and incoherent random noise are not commensurate, thus requiring different mathematical treatment and analysis. Also described are the different causes and ways of analysis of ambient microseismic noise as recorded at stations on land in the very wide frequency range between some mHz and 100 Hz. The article sketches some essential procedures of noise reduction by way of proper sensor shielding and installation, also at depth, as well as feature and problem adapted filtering aimed at improved signal-to-noise ratio and thus signal detection and identification. Many references for further readings are given, amongst them to relevant IASPEI Manual articles accessible via <http://nmsop.gfz-potsdam.de>.

A Perspective into the Seismic Reliability Assessment

The treatment of structural behavior under seismic actions can be considered as one of the most challenging aspects of structural performance assessment and design. It encompasses numerous

sources of uncertainty associated with the seismic action, structural response, and structural capacities. The various parameters involved in the seismic performance assessment problem can be generically designated in terms of seismic *demand* (D) and *capacity* (C) of the structure. The seismic demand and capacity can be characterized as a functional (i.e., function of function) of a set of *uncertain parameters* (also denoted as “random variables”). Hence, probabilistic methods are necessary in order to take into account the uncertainties in demand and capacity within the performance assessment or design.

Traditionally, seismic-design codes have addressed the uncertainties by allowing some degree of conservatism in evaluating demand and capacity at the level of structural components; nevertheless, the link to the overall performance of the structure remains unclear. Strictly speaking, the reliability of the structure to withstand future events remains more-or-less unknown to the designer while employing various established code-based approaches. Therefore, in the past decades, several research efforts have been carried out and substantial progress has been made towards the inclusion of various sources of uncertainty into structural performance assessment and design frameworks.

This entry introduces the main sources of uncertainty in demand and capacity, as well as their treatments through alternative reliability methods. In this regard, three general families of methods are briefly summarized in this entry: the second-moment reliability methods, the simulation-based reliability approaches, and finally the probabilistic performance-based methodology developed within the joint efforts of Pacific Earthquake Engineering Research Center (PEER). The closing section provides a brief discussion about future challenges in seismic reliability assessment.

An Introduction to Seismic Reliability Assessment

Seismic structural reliability is concerned with the probabilistic performance evaluation of

structures under seismic actions. This issue is addressed by means of defining a prescribed set of *limit states*, which describe specific stages of structural behavior and its consequences (e.g., states associated with consequences in terms of costs, loss of lives, impact on the environment, or serviceability; see Bozorgnia and Bertero 2004). Reaching a limit state denotes that an unacceptable behavior for the structure occurs. This condition is generically referred to as *failure*. The limit state exceedance is verified by comparing a measurable quantity, associated with the structural response, denoted as the *demand* D (also referred to as the engineering demand parameter (EDP), e.g., maximum inter-story drift ratio, maximum chord rotation, maximum component shear, etc.), with the corresponding limit value, denoted as the *capacity* C (e.g., yielding rotation, ultimate rotation, shear strength, etc.). As a result, the inequality $D \leq C$, also called *safety margin formulation*, defines acceptable performance respect to the current limit state in mathematical terms (Pinto et al. 2007). This formulation is generally expressed as *limit state function* (or *performance function*) $G = C - D$. This type of formulation is also employed in the *load and resistance factor design* (LRFD) format (Galambos et al. 1982), which is familiar to engineers as the safety checking equation. As an alternative to the safety margin formulation, the *safety factor formulation* is introduced as $G = \ln(C/D)$ (DNV 1992). For both the *safety margin formulation* and the *safety factor formulation*, failure is defined as $G \leq 0$.

As mentioned before, the evaluation of the structural performance in terms of demand and capacity may encompass several sources of uncertainty. In such context, the performance with respect to a given limit state is evaluated in terms of the probability that the limit state function will be less than zero (*probability of failure* P_F) in a specified reference time period. Identifying $\mathbf{X} = [X_1, X_2, \dots, X_n]$ to be the group of n uncertain parameters involved in the reliability problem, the probability of failure may be determined by the following integral:

$$P_F = P[G(\mathbf{X}) \leq 0] = \int_{G(\mathbf{X}) \leq 0} f_{\mathbf{X}}(\mathbf{X}) d\mathbf{x} \quad (1)$$

where $f_{\mathbf{X}}$ is the joint probability distribution for uncertain parameters $\mathbf{X}$. This means that one can evaluate the probability of failure by integrating the joint density function over the failure domain defined as $G(\mathbf{X}) \leq 0$.

Conventionally, the *generalized reliability* (or *safety*) index β associated with a given limit state function is defined by one-to-one mapping relationship with failure probability as follow:

$$\beta = -\Phi^{-1}(P_F) \quad (2)$$

where $\Phi(\cdot)$ is the standard normal Cumulative Distribution Function (CDF). Equation 2, however, does not mean to imply that uncertain parameters are jointly normal. The inverse of the standard normal CDF simply provides a convenient one-to-one mapping between the computed probability of failure and a reliability index.

The evaluation of the integral in Eq. 1 can be computationally difficult; some examples are as follows: $f_{\mathbf{X}}$ is often not well-defined because of the incompleteness of the statistical information available; $G(\mathbf{X})$ may have a nonlinear form; the computation of the multifold integral can be very difficult if the number of uncertain parameters is high. Various methods have been proposed for solving the integral form in Eq. 1. These approaches range from the classical moment methods for structural reliability (e.g., first-order second-moment reliability method) to the simulation-based approaches (i.e., Monte Carlo family of methods), and also the PEER approach, which is quite different compared to the other two techniques. In this entry, alternative methods for estimating the probability of failure are described.

Types of Uncertainty

There are alternative ways for classifying the sources of uncertainty. Arguably, such classification depends to some extent on the reliability method adopted. Some classical reliability

methods provide the following classification of uncertainties in seismic structural engineering: (1) *inherent randomness* due to the intrinsic variability in material mechanical properties as well as environmental actions (i.e., loads or seismic excitation); (2) *statistical uncertainties* due to the lack of knowledge associated with the estimation of the parameters of probability distributions from observational samples of limited size; and finally (3) *model uncertainties* due to the imperfections of the mathematical models used to describe complex physical phenomena (i.e., model describing load or element capacity) (see also Der Kiureghian 1996; Ditlevsen and Madsen 1996). Some other reliability methods (mostly simulation based) classify the sources of uncertainty into two general categories: those related to the representation of the seismic action and those related to the structural modeling (see, e.g., Papadimitriou et al. 2001). Another useful classification is based on the definition of the *aleatory* and *epistemic* uncertainties (Cornell et al. 2002; Der Kiureghian and Ditlevsen 2009). These two categories are also known as *inherent* randomness (i.e., uncertainty impossible to mitigate) and *statistical* uncertainties (i.e., uncertainties that can be mitigated with reasonable effort), respectively (McGuire 2004). On the other hand, in the Bayesian probabilistic framework, the various sources of uncertainty are treated in a unified manner. In subsequent sections, the uncertainties in the seismic reliability problems are divided (if required) into those related to the representation of the seismic action, also referred to as the record-to-record (RTR) variability, and other sources of uncertainty. As mentioned above, the set of uncertain parameters involved in the seismic performance assessment or design problem are denoted hereafter by the vector of parameters $\mathbf{X}$.

Structural Component and Structural System Reliability

A *structural component* is a basic structural element whose performance is defined by a single limit state function $G(\mathbf{X}) = 0$ (Fig. 1a). In the hyperspace of the designated uncertain parameters $\mathbf{X}$, the limit state function represents the

Seismic Reliability Assessment, Alternative Methods for, Fig. 1 Reliability problems for the special case of only two uncertain parameters x_1 and x_2 : (a) Component,

(b) series system, (c) parallel system. The gray shaded area represents the side of the failure domain

boundary (i.e., *limit state surface*) between safe and failure zones (the latter is also called the *failure domain*), as shown in Fig. 1a for the special case of only two uncertain variables (Ditlevsen and Madsen 1996).

A *structural system* is an assemblage of components, whose performance is described by individual component limit state function. Therefore, in a structural system reliability problem, the failure domain may be described as the union and/or intersection of several limit state surfaces. In particular, a *series system* (also known as the *weakest-link*) reliability problem is defined as the union of the failure domains (Fig. 1b), and a *parallel system* reliability problem is defined as the intersection of the failure domains (Fig. 1c). In analytic terms, the probability of failure for series and parallel systems with n components is defined, respectively, as

$$P_{F, \text{series}} = P \left[\bigcup_{i=1}^n (G_i(\mathbf{X}) \leq 0) \right] \quad P_{F, \text{parallel}} = P \left[\bigcap_{i=1}^n (G_i(\mathbf{X}) \leq 0) \right] \quad (3)$$

A cut-set is made as a combination of series and parallel systems generating a *generalized system* reliability problem. A cut-set (Fig. 2) is any set of components whose joint failure represents a failure of the system (Ditlevsen and Madsen 1996; Au and Beck 2003b; Jalayer et al. 2007a). Analytically, the probability of failure for a cut-set system is evaluated as

Seismic Reliability Assessment, Alternative Methods for, Fig. 2 Reliability problems for the special case of only two uncertain parameters x_1 and x_2 : cut-set system. The gray area represents the side of the failure domain

$$P_{F, \text{cut-set}} = P \left[\bigcup_{j=1}^N \bigcap_{i=1}^{n_j} (G_i(\mathbf{X}) \leq 0) \right] \quad (4)$$

where N defines the associated number of the subsystem that is connected in series to the other subsystems and n_j is the number of components connected in parallel belonging to the j th subsystem.

Seismic Reliability Assessment, a Time Variant Nonlinear Problem

If the limit state function reveals time-dependent properties, then the reliability problem can be referred to as *time variant*. Hence, given the stochastic nature of the seismic excitation, the seismic reliability assessment can be classified as a

time-variant problem. Therefore, the failure event constitutes the outcrossing of the time-variant limit state surface. This represents the so-called *first-passage* (or *first-excursion*) problem (e.g., Au and Beck 2001b). Moreover, in many practical cases, the limit state function is nonlinear. Therefore, the seismic reliability problems can be classified, in general, as time-variant nonlinear problems.

The Second-Moment Reliability Methods

In general, the n^{th} moment of a mono-variate distribution (i.e., a distribution with a single scalar random variable) is defined as the expected value of the variable raised to the power of n . Using moments of finite order for describing the uncertainty in given parameter is a well-known problem in statistics referred to as the *moment methods*. A comprehensive review of the *moment methods* in the structural reliability analysis is presented in Zhao and Ono (2001). The second-moment reliability methods can be dated back to the 1960s (some historical notes can be found in Ditlevsen and Madsen 1996). Since then, this family of methods has been refined and extended significantly. At present, they represent one of the most important and widespread approaches for seismic reliability evaluation of structures. As reflected by their title, the second-moment reliability methods employ the first two moments of the vector of uncertain parameters $\mathbf{X}$ (i.e., expected value $\mathbb{E}[\mathbf{X}]$ and covariance $\Sigma_{\mathbf{X}}$).

Linear (First-Order) Limit State Function and Its First Second Moments

The simplest mathematical form for a performance function is the linear (first-order) polynomial:

$$G(\mathbf{X}) = a_0 + a_1 X_1 + \dots + a_n X_n = a_0 + \mathbf{a}^T \mathbf{X} \quad (5)$$

where the coefficients a_0 and $\mathbf{a} = [a_1, \dots, a_n]$ are constants. It is possible to write the two central

moments of $G(\mathbf{X})$ in terms of the first two (central) moments of the vector of uncertain parameters $\mathbf{X}$:

$$\begin{aligned} \mu_G &= \mathbb{E}[G(\mathbf{X})] = a_0 + \mathbf{a}^T \mathbb{E}[\mathbf{X}] = a_0 + \mathbf{a}^T \boldsymbol{\mu}_{\mathbf{X}} \\ \sigma_G^2 &= \mathbb{E}[(G(\mathbf{X}) - \mu_G)^2] \\ &= \mathbf{a}^T \mathbb{E}[(\mathbf{X} - \boldsymbol{\mu}_{\mathbf{X}})(\mathbf{X} - \boldsymbol{\mu}_{\mathbf{X}})^T] \mathbf{a} = \mathbf{a}^T \Sigma_{\mathbf{X}} \mathbf{a} \end{aligned} \quad (6)$$

One of the simplest forms of reliability measure was proposed by Cornell (1969), in which the second-moment reliability index is defined as the ratio between the mean value and the standard deviation of the performance function G (i.e., the so-called “Cornell index”):

$$\beta = \frac{\mu_G}{\sigma_G} \quad (7)$$

Assuming that the unacceptable performance is reached when $G \leq 0$, it is possible to establish a one-to-one mapping between the Cornell index and the probability of failure, as already shown in Eq. 2:

$$\begin{aligned} P_F &= P[G(\mathbf{X}) \leq 0] \\ &= P\left[\frac{G(\mathbf{X}) - \mu_G}{\sigma_G} \leq \frac{0 - \mu_G}{\sigma_G}\right] \\ &= \Phi\left(-\frac{\mu_G}{\sigma_G}\right) = \Phi(-\beta) \end{aligned} \quad (8)$$

This mapping is exact if the variables are normal. Otherwise, Eq. 8 returns an approximate value of the failure probability.

First-Order Second-Moment (FOSM) Method in Component Reliability

In the case of a nonlinear limit state surface, the reliability index fails to be constant under different but mechanically equivalent formulations of the performance function. The issue of a lack of invariance was first recognized by Ditlevsen (1973) and later resolved by Hasofer and Lind (1974). In order to overcome this issue, they proposed the transformation of the uncertain

Seismic Reliability Assessment, Alternative Methods for, Fig. 3 The limit state function and the joint-normal PDF of the uncertain parameters in (a) nonstandard space of correlated uncertain parameters and (b) standard space of the uncorrelated uncertain parameters

parameters $\mathbf{X}$ into a set of uncorrelated standard normal deviates (variables) $\mathbf{U}$ (i.e., $\boldsymbol{\mu}_U = \mathbf{0}$, $\boldsymbol{\Sigma}_U = \mathbf{I}$). To this aim, the basic random variables, $\mathbf{X}$, can be transformed into a set of uncorrelated standard variates $\mathbf{U}$ through the linear transformation:

$$\mathbf{U} = \mathbf{L}_X^{-1} \mathbf{D}_X^{-1} (\mathbf{X} - \boldsymbol{\mu}_X) \quad \text{or} \quad \mathbf{X} = \mathbf{D}_X \mathbf{L}_X \mathbf{U} + \boldsymbol{\mu}_X \quad (9)$$

where $\mathbf{D}_X$ is diagonal matrix of the standard deviations of the basic random variables and $\mathbf{L}_X$ is the lower triangular matrix obtained as the Cholesky decomposition of the correlation coefficient matrix $\mathbf{R}_X$ (i.e., $\mathbf{R}_X = \mathbf{L}_X \mathbf{L}_X^T$). It is then possible to define the joint-normal PDF $\phi_U(\mathbf{u})$ and $g(\mathbf{U}) = G[\mathbf{X}(\mathbf{U})]$ as the joint-normal distribution of the uncertain parameters and the limit state function, respectively, transformed in the space of the standard uncorrelated variables (Fig. 3). By considering a linear performance surface (see Eq. 5), $g(\mathbf{U})$ can be expressed as

$$\begin{aligned} g(\mathbf{U}) &= G[\mathbf{X}(\mathbf{U})] = a_0 + \mathbf{a}^T (\mathbf{D}_X \mathbf{L}_X \mathbf{U} + \boldsymbol{\mu}_X) \\ &= a_0 + \mathbf{a}^T \boldsymbol{\mu}_X + \mathbf{a}^T \mathbf{D}_X \mathbf{L}_X \mathbf{U} = b_0 + \mathbf{b}^T \mathbf{U} \end{aligned} \quad (10)$$

It can be easily demonstrated that the first and second moments of this performance function are $\mu_g = b_0$ and $\sigma_g^2 = \mathbf{b}^T \mathbf{b}$. Substituting these two terms in Eq. 7, the reliability index in the standard space can be obtained as follows:

$$\beta = \frac{\mu_g}{\sigma_g} = \frac{b_0}{\sqrt{\mathbf{b}^T \mathbf{b}}} \quad (11)$$

The reliability index in Eq. 11 can be interpreted as the distance from the origin to the hyperplane (in standard normal space) defined by $b_0 + \mathbf{b}^T \mathbf{U} = 0$. In other words, the reliability index for a linear limit state function is numerically equivalent to the distance from the origin to the limit state hyperplane in the space of the standard normal variables. Using this geometric interpretation, Hasofer and Lind (1974) defined the reliability index as the minimum distance between the origin of standard normal space and the function $g(\mathbf{U})$ (Fig. 4a).

The point $\mathbf{U}_0$ belonging to the limit state surface that has the minimum distance from the origin of standard normal space is called *design point* (or *performance point*). The latter is the most likely failure point. Strictly speaking, $\mathbf{U}_0$ is the vector of uncertain parameters that has the maximum contribution towards the failure probability.

As also mentioned before, the limit state function is generally nonlinear. Therefore, the function $g(\mathbf{U})$ usually cannot be characterized by a first-order polynomial. An approximate way to solve this problem is to replace the nonlinear function with a first-order Taylor series expansion. In other words, the performance surface, in the neighborhood of the design point $\mathbf{U}_0$, is approximated by the tangent hyperplane at $\mathbf{U}_0$ (Fig. 4b). In analytical terms, the approximate limit state function $g_F(\mathbf{U})$ becomes

$$g_F(\mathbf{U}) = g(\mathbf{U}_0) + \nabla g^T(\mathbf{U}_0) \cdot (\mathbf{U} - \mathbf{U}_0) \quad (12)$$

where $\nabla g(\mathbf{U}_0)$ is the gradient of g evaluated at the performance point and the subscript F represents

Seismic Reliability Assessment, Alternative Methods for, Fig. 4 Different types of limit state surface and their approximations: (a) linear, (b) nonlinear with linear

approximation, $g_F(\mathbf{U}) = 0$ at performance point, (c) nonlinear surface approximated with a paraboloid, $g_S(\mathbf{U}) = 0$

the first-order approximation to g . In particular, the first two moments of $g(\mathbf{U})$ can be calculated as follows (by using the relationships in Eq. 6):

$$\begin{aligned}\mu_g &= g(\mathbf{U}_0) + \nabla g^T(\mathbf{U}_0)(\boldsymbol{\mu}_{\mathbf{U}} - \mathbf{U}_0) \\ &= -\nabla g^T(\mathbf{U}_0)(\boldsymbol{\mu}_{\mathbf{U}} - \mathbf{U}_0)\sigma_g^2 \\ &= \nabla g^T(\mathbf{U}_0)\boldsymbol{\Sigma}_{\mathbf{U}}\nabla g(\mathbf{U}_0) \\ &= \nabla g^T(\mathbf{U}_0)\nabla g(\mathbf{U}_0)\end{aligned}\quad (13)$$

where $g(\mathbf{U}_0)$ is equal to zero since $\mathbf{U}_0$ is on the limit state function, and the mean is equal to zero ($\boldsymbol{\mu}_{\mathbf{U}} = 0$) and the covariance is equal to one ($\boldsymbol{\Sigma}_{\mathbf{U}} = \mathbf{I}$) by definition. For a nonlinear performance function, the first-order reliability index can be defined as equal to the distance of the linearized failure surface (at the performance point $\mathbf{U}_0$) to the origin of the standardized uncorrelated variables (Fig. 3b). With reference to Eq. 12, it is possible to calculate the first two moments of the linearized limit state function (according to Eq. 13) and obtain the following reliability index (in literature also referred to as first-order second-moment reliability index β_{FOSM} or Hasofer-Lind reliability index β_{HL}):

$$\beta = \frac{\mu_g}{\sigma_g} = \frac{-\nabla g^T(\mathbf{U}_0) \cdot \mathbf{U}_0}{\sqrt{\nabla g(\mathbf{U}_0)^T \nabla g(\mathbf{U}_0)}} = \boldsymbol{\alpha}^T \cdot \mathbf{U}_0 \quad (14)$$

where $\boldsymbol{\alpha}$ is the unit normal (directed towards the failure region) on the hyperplane that is tangent to the limit state surface at the performance

point $\mathbf{U}_0$ (Fig. 3b). The components of $\boldsymbol{\alpha}$ are called the sensitivity factors of the reliability index β with respect to uncertain parameters $\mathbf{U}$. The smaller is α_i , the smaller is the contribution of the related uncertain parameter U_i to the failure probability assessment.

Clearly, the determination of β requires the finding of the design point $\mathbf{U}_0$. Therefore, one has to solve the following constrained optimization problem:

$$\begin{cases} \beta = \min|\mathbf{U}| \\ g(\mathbf{U}) = 0 \end{cases} \quad (15)$$

There are many algorithms that are able to solve this kind of problems (see, e.g., Liu and Der Kiureghian 1991). The most common algorithm used in structural reliability is the one developed by Rackwitz and Flessler (1978). A comprehensive description of the algorithm and relevant examples can be found in Pinto et al. (2007), while a first review of the efficiency of the available algorithms was presented in Liu and Der Kiureghian (1991). Once β is determined, the probability of failure can be approximated by Eq. 8.

Extension to System Reliability

It is noteworthy that in order to compute a system reliability problem, one must be able to compute (or approximate) the probability of a union of N events (series system) or the probability of an intersection of N events (parallel systems). The probability of failure for these two cases

can be approximated as (Hohenbichler and Rackwitz 1983)

$$P_{F,\text{series}} \approx 1 - \Phi_N(\boldsymbol{\beta}, \mathbf{R}) \quad P_{F,\text{parallel}} \approx \Phi_N(-\boldsymbol{\beta}, \mathbf{R}) \quad (16)$$

where Φ_N is the multi-normal CDF, $\boldsymbol{\beta}$ is the N -vector of the reliability indexes associated with the structural components, and $\mathbf{R}$ is the $N \times N$ correlation matrix, in which the correlation coefficients, $\rho_{ij} = \alpha_i^T \alpha_j$, quantify the correlation between failure modes i and j . In general, the evaluation of $\Phi_N(\boldsymbol{\beta}, \mathbf{R})$ and $\Phi_N(-\boldsymbol{\beta}, \mathbf{R})$ in Eq. 16 is not trivial; however, an efficient Monte Carlo simulation algorithm has been developed for this purpose (Ambartzumian et al. 1998). The previous results can be combined to estimate the probability of failure of a general system (Ditlevsen and Madsen 1996).

FORM and SORM Method in Component Reliability

For the reliability index presented so far, only the two moments of each uncertain parameter have been considered. However, in many applications, information beyond the second moments is available. The methods that make use of that additional information are called *full distribution reliability methods*. If the probability distribution is available for some or all the basic variables, it would be sensible to incorporate it in the reliability analysis. If the joint probability distribution for the vector of uncertain parameters in the original space is not normal and the variables are not independent, the multifold integral presented in Eq. 1 becomes very hard to solve. In fact, several efficient methods for approximating the integral take advantage of the special properties of the standard normal distribution of uncorrelated variables. Therefore, the transformation of independent/dependent non-normal uncertain parameters to independent joint-normal uncertain parameters is quite important.

Historically, the transformation approach was developed as an extension of the FOSM and is

therefore often called *advanced* or *extended* FOSM, since the limit state function is approximated with a first-order approximation, while the probability distributions are no longer approximated only with the first two central moments. In particular, if the limit state function is approximated with its first-order Taylor expansion, these methods are known as FORM (*First-Order Reliability Methods*), and the analytical relations to calculate the reliability index are similar to those reported from Eqs. 12 to 15. If the limit state function is approximated with its second-order Taylor expansion, these methods are known as SORM (*Second-Order Reliability Methods*). In both cases, the Taylor expansion is done at the *design point* $\mathbf{U}_0$.

A SORM analysis reduces the error associated with the non-flatness of the limit state function at the design point in a FORM approximation. In particular, this approach fits a second-order surface (usually a paraboloid) at the performance point as shown in Fig. 4c. A parabolic approximation to the limit state surface at the design point is

$$g_S(\mathbf{U}) = g(\mathbf{U}_0) + \nabla g^T(\mathbf{U}_0) \cdot (\mathbf{U} - \mathbf{U}_0) + \frac{1}{2}(\mathbf{U} - \mathbf{U}_0)^T \mathbf{H}(\mathbf{U}_0)(\mathbf{U} - \mathbf{U}_0) \quad (17)$$

where $\mathbf{H}(\mathbf{U}_0)$ is the Hessian matrix of g evaluated at $\mathbf{U}_0$ and the subscript S denotes the approximation to the second order of g . In this case, it is more difficult to express the first two moments of the limit state function (for more details, see Pinto et al. 2007); instead, the probability of failure is approximated in terms of β and the $n-1$ principal curvatures κ_i of the paraboloid in the standardized uncorrelated n -space defined by vector $\mathbf{U}$. The exact expression of this probability is given in terms of single-fold integral defined by Tvedt (1990) which can be solved numerically in lack of closed-form solution. A simpler approximation was derived on the basis of asymptotic analysis by Breitung (1984):

$$P_F \approx \Phi(-\beta) \prod_{i=1}^{n-1} \frac{1}{\sqrt{1 + \beta \kappa_i}} \quad (18)$$

where β is calculated as the minimum distance between the origin of the standard normal space and the paraboloid.

Reliability Methods in Design Codes: The Safety Factors in LRFD

Until the 1960s, most design codes did not provide an explicit implementation of reliability concepts. The recommended methods mainly involved stress checks in critical sections, which aimed to verify that the unit stresses under the action of working, or service, loads do not exceed predesignated allowable values (i.e., values prescribed by the building code to provide a factor of safety against attainment of some limiting stress, such as the minimum specified yield stress or the stress at which the buckling occurs); this design philosophy is also known as the working stress design. The issue of uncertainty in the various parameters was implicitly addressed by employing safety factors much larger than unity on the material strength. During the 1960s and 1970s, reliability analyses were addressed more explicitly by the codes, giving rise to reliability-based design. However, because professional design engineers found the application of the reliability-based methods somewhat difficult to access, a *semi-probabilistic* code-based approach known as the *load and resistance factor design* (LRFD) format was proposed (Galambos et al. 1982):

$$R/\gamma_R \geq \gamma_S \cdot S \quad \text{or} \quad R_d \geq S_d \quad (19)$$

where R_d and S_d are the design resistance and load, respectively; R and S are the nominal resistance and nominal action (due to loads); and γ_R and γ_S are the associated resistance and load safety factors. The codes aim to link these coefficients with the target (admissible) reliability and with the amount of uncertainty in each uncertain parameter. The two safety factors in Eq. 19 have the general form

$$\gamma_R = \frac{\mu_R}{R} (1 + \alpha'_R \beta \delta_R) \quad \text{or} \quad \gamma_S = \frac{\mu_S}{S} (1 + \alpha'_S \beta \delta_S) \quad (20)$$

where μ_R and μ_S denote the mean resistance and load; α'_R and α'_S are the sensitivity coefficients (function of the sensitivity factors presented in Eq. 14) for the resistance and load corresponding to R and S , respectively; β is the FOSM reliability index associated to the target reliability (obtained from the inverse of the standard normal cumulative distribution); and finally, δ_R and δ_S are the coefficient of variation (i.e., the standard deviation divided by the mean) of the resistance and load. For example, assuming that the nominal values are equal to the mean values, it can be observed that the safety factor is only a function of α , β , and δ .

Clearly, the safety factors depend on the chosen limit states. For the ultimate limit state, for instance, most of design codes provide safety factors that are calibrated with respect to nominal values. These nominal values are chosen as the value with a predefined probability of being exceeded; typically a lower (usually 5 %) percentile is selected for the resistance and an upper (usually 95 %) percentile is selected for the load effect. The European standard (CEN 2002) and ASCE standard (ASCE 2010) both define the acceptable values of the reliability index. In particular, the European standard defines minimum values that are established as a function of the consequences related to the reaching of a given limit state (with β varying from 3.3 to 4.3 with respect to 50 years of service period), whereas the ASCE standard defines the acceptable reliability index (which is related to a specified failure probability) as a function of the structural damage and occupancy category of the construction (with β varying from 2.5 to 4.5 for 50 years of service period). This approach, however, allows for reliability checking at the member level rather than at the system level. As mentioned before, establishing the link between component reliability and system reliability is not a trivial problem.

Alternative Methods Based on Time-Invariant Reliability Methods

When an equivalent linear static procedure or a response spectrum analysis is performed, the

reliability analysis can be carried out in a straightforward manner using the time-invariant reliability methods. However, in the case of dynamic nonlinear analyses, the problem becomes much more complicated. In fact, in the latter case, it is generally difficult to express the limit state of interest directly in terms of time-invariant basic load and resistance uncertain parameters. Therefore, the combination of the different source of uncertainties becomes an intricate problem to tackle. Nowadays, it is possible to combine the reliability methods and the finite element analysis to overcome this problem (Der Kiureghian 1996). Currently, useful specialized software is available to address this issue (Der Kiureghian et al. 2006). Alternatively, a few *hybrid* approaches have been recently proposed in order to address the time variance in reliability problem.

These methods combine the RTR variability (taken into account by alternative methods like the PEER approach, which is discussed subsequently in this entry) with other source of uncertainties (treated by current FORM/SORM reliability methods). Typical hybrid approaches consist of the confidence interval approach (Cornell et al. 2002; Ellingwood and Kinali 2009) and the mean estimate approach (Cornell et al. 2002). Other relevant examples can be found in Ibarra and Krawinkler (2005), Haselton and Deierlein (2007), Dolšek (2009), Liel et al. (2009), Vamvatsikos and Fragiadakis (2010), and Celarec and Dolšek (2013). In these studies, many approximations are presented; for instance, if the limit state function does not have a defined functional form, the required gradients of the linearized limit state function can be obtained through perturbation of individual uncertain parameters in a series of sensitivity analyses.

Simulation-Based Reliability Methods

The general integral form in Eq. 1 can also be estimated by employing various simulation techniques. These techniques are especially efficient when the limit state function is non-differentiable

or has several design points that make significant contributions to the failure probability (Faber 2012; Pinto et al. 2007). Although a large variety of simulation techniques may be found in the literature, they generally have their origin in the so-called *Monte Carlo* (MC) method (Rubinstein 1981; Fishman 1996). The general principles of standard MC simulation technique are outlined in the following section. To have a further insight into the basis of simulation techniques, the probability integral in Eq. 1 is rewritten as follows:

$$P_F = \int_{\Omega_{\mathbf{x}}} I_F(\mathbf{x}) f_{\mathbf{x}}(\mathbf{x}) d\mathbf{x} = \mathbb{E}[I_F(\mathbf{X})] \quad (21)$$

where $\Omega_{\mathbf{x}}$ denotes the entire sample space of $\mathbf{X}$ and $I_F(\mathbf{x})$ is an indicator function that equals one when $G(\mathbf{x}) \leq 0$ and zero otherwise. The integral in Eq. 21 is the expected value of the indicator function denoted as $\mathbb{E}[I_F(\mathbf{x})]$. In other words, P_F is the expected value of $I_F(\mathbf{x})$ based on the joint PDF $f_{\mathbf{x}}(\mathbf{x})$. It is noteworthy that throughout section “[Simulation-Based Reliability Methods](#),” $p(\mathbf{x})$ might be used in place of $f_{\mathbf{x}}(\mathbf{x})$ interchangeably. This is done in order to homogenize and to simplify the probability notations within different equations. Hence, the term $p(\mathbf{x})$ is used in cases where the conditioning on a preposition is defined, the use of $f_{\mathbf{x}}$ might create further confusions, or in the robust reliability expressions defined subsequently in section “[Robust Reliability Assessment Using Simulation-Based Approaches](#).” However, the marginal PDFs are expressed generally by $f_{\mathbf{x}}$. By employing the MC method, various realizations of the uncertain parameters $\mathbf{x}$ (i.e., $\mathbf{x}_k$, $k = 1: N_S$) can be independently sampled so that the multidimensional integral in Eq. 21 is estimated as follows:

$$P_F = \mathbb{E}[I_F(\mathbf{X})] \cong \frac{1}{N_S} \sum_{k=1}^{N_S} I_F(\mathbf{x}_k) = \frac{N_F}{N_S} \quad (22)$$

where N_S is the total number of simulations and N_F is the number of realizations for which $I_F(\mathbf{x}_k) = 1$ (i.e., the realizations leading to failure).

It can be shown that Eq. 22 is an unbiased estimator for P_F since

$$\mathbb{E}(\mathbb{E}[I_F(\mathbf{X})]) = \frac{1}{N_S} \sum_{k=1}^{N_S} \mathbb{E}[I_F(\mathbf{x}_k)] = \frac{N_S P_F}{N_S} = P_F \quad (23)$$

The variance of the estimator can be calculated by considering that $I_F(\mathbf{x}_k)$'s are independently distributed Bernoulli variables with variance equal to $P_F(1-P_F)$:

$$\begin{aligned} \text{VAR}(\mathbb{E}[I_F(\mathbf{X})]) &= \text{VAR}\left(\frac{1}{N_S} \sum_{k=1}^{N_S} I_F(\mathbf{x}_k)\right) \\ &= \frac{N_S P_F (1 - P_F)}{N_S^2} \\ &= \frac{P_F (1 - P_F)}{N_S} \end{aligned} \quad (24)$$

This equation reveals that the uncertainty in the estimator decreases with increasing N_S . Therefore, in order to accurately quantify the likelihood of rare events (with small P_F), which is a characteristic feature in seismic assessment, N_S should be increased. Besides the integral form in Eq. 21 for the structural reliability formulation, many problems in probabilistic inference require the calculation of multidimensional integrals or summations over very large outcome spaces. In the general form, they can be expressed as

$$R = \int_{\Omega_{\mathbf{x}}} h(\mathbf{x}) f_{\mathbf{x}}(\mathbf{x}) d\mathbf{x} = \mathbb{E}[h(\mathbf{X})] \quad (25)$$

where R is a performance measure of interest and $h(\mathbf{x})$ is a response quantity of interest. The general idea of MC integration is used to approximate the expectation. Hence, a set of N_S samples can be drawn independently from distribution $p(\mathbf{x})$, and the expectations can be approximated by a finite sum:

$$R = \mathbb{E}[h(\mathbf{X})] \cong \frac{1}{N_S} \sum_{k=1}^{N_S} h(\mathbf{x}_k) \quad (26)$$

In this procedure, the analytic integration is replaced with summation over a suitably large set of samples. Generally, the approximation can be made as accurate as needed by increasing N_S .

Fundamentals of MC Method

The MC family of methods employs various sampling techniques in order to generate realizations of the prescribed uncertain parameters. The standard MC simulation uses the random sampling approach in order to generate a large amount of realizations of uncertain parameters. The probability of failure can then be estimated by directly implementing Eq. 22 regardless of the complexity of the problem. Checking whether the structure has failed for each sample usually requires a structural analysis. To simulate $k = 1:N_S$ outcomes of the joint density function (corresponding to Eqs. 21–22 or Eqs. 25–26) in standard MC simulation, a random number, denoted as $z_{j,k}$, between 0 and 1 is generated for each of the components in $\mathbf{x}_k$ (i.e., $x_{j,k}$, $j = 1:n$). Assuming that X_j 's are independent, the random numbers $z_{j,k}$ are mapped to $x_{j,k}$ by

$$x_{j,k} = F_{X_j}^{-1}(z_{j,k}) \quad (27)$$

where F_{X_j} is the marginal Cumulative Distribution Function (CDF) associated with the uncertain parameter X_j . Generally, the standard MC simulation is not justifiable computationally for adequate estimation of very small failure probabilities as a very large number of simulations are required.

The Latin hypercube sampling technique (LHS; Helton and Davis 2003) can be employed in order to reduce the number of simulations, N_S , in addition to achieving an acceptable level of accuracy for the statistical characteristics of response. The LHS is a special type of MC simulation that uses the stratification of the theoretical CDFs of uncertain parameters. Stratification divides the CDF curve into N_S equal intervals on the probability scale (i.e., 0.0 to 1.0). A sample is then randomly drawn from each interval or “stratification” of the input CDFs based on the

technique of “sampling without replacement.” According to this technique, once a sample is taken from a designated stratification, this stratification is not sampled again.

As a result, the samples based on LHS reflect more accurately the distribution of values in the input probability distribution. LHS offers great benefits in terms of increased sampling efficiency and faster runtimes (due to fewer N_S that is required). Its roles in different aspects of reliability engineering have been described by, e.g., Novák et al. (1998) and Olsson et al. (2003). Stein (1987) has shown that the LHS reduces the variance of the response function compared to the crude Monte Carlo method.

Various methodologies were proposed for sampling based on LHS method; however, the most efficient strategy to perform sample selection, which deals also with samples of the tails of the PDF, is the sampling of interval mean values denoted as LHS mean (Huntington and Lyrintzis 1998). In this context, consider that the range of probability distribution F_{X_j} between 0.0 and 1.0 is divided into N_S equidistant intervals each with equal probability of $1/N_S$. The expression $\xi_{j,k}$ is the value of the uncertain parameter associated with the k th stratification with the probability k/N_S where $k = 1:N_S$:

$$\xi_{j,k} = F_{X_j}^{-1}(k/N_S) \quad (28)$$

The sampled data $x_{j,k}$ within the interval $[\xi_{j,k-1}, \xi_{j,k}]$ can be derived as

$$\begin{aligned} x_{j,k} &= \frac{\int_{\xi_{j,k-1}}^{\xi_{j,k}} x f_{X_j}(x) dx}{\int_{\xi_{j,k-1}}^{\xi_{j,k}} f_{X_j}(x) dx} \\ &= N_S \int_{\xi_{j,k-1}}^{\xi_{j,k}} x f_{X_j}(x) dx, \quad j = 1, \dots, n, \\ &\quad k = 1, \dots, N_S \end{aligned} \quad (29)$$

where f_{X_j} is the PDF of the uncertain parameter X_j . In spite of high efficiency of LHS technique, there are generally two issues concerning

statistical correlation (Vořechovský and Novák 2009): (1) diminishing undesired and spurious correlation between uncertain parameters generated during sampling procedure, particularly in the case of a very small number of simulations, and (2) introducing the prescribed statistical correlations between pairs of uncertain parameters defined by the target correlation. Hence, in order to impose a prescribed correlation into the sampling scheme, an optimization problem for minimizing the difference between the target correlation and the actual correlation (estimated from samples) should be solved. For this purpose, a stochastic optimization approach called simulated annealing (SA) has been recently proposed (Vořechovský and Novák 2009; Golafshani et al. 2011) for application of LHS together with the SA methodology in structural reliability assessment).

The main drawback of the standard MC simulation methods is that it is not computationally efficient for problems dealing with small probabilities of failure (i.e., $P_F \leq 10^{-3}$). The main reason is due to the fact that the number of samples and hence the number of structural analyses, which are required to achieve a given accuracy, is inversely proportional to P_F . It requires information from rare samples that lead to failure, and on average, many samples are required before one such failure sample occurs. For instance, in case of achieving the P_F in order of 10^{-4} (which is typical in seismic reliability assessment) with a coefficient of variation around 10 %, nearly 10^6 simulations are required. Essentially, for rare events, the chance of generating samples from $f_{\mathbf{X}}(\mathbf{x})$ for which $I_F(\mathbf{x})$ equals one is extremely small (i.e., success rate is slow); therefore, many samples are needed to fulfill this requirement.

To overcome this obstacle, different techniques have been proposed in order to reduce the number of simulations. One of the most commonly applied techniques is namely the *importance sampling* method, which is described in the next section.

Importance Sampling Simulation Technique

The underlying idea of the importance sampling simulation (Rubinstein 1981; Shinozuka 1983;

Schuëller and Stix 1987; Au and Beck 1999) is to carry out Monte Carlo simulation with samples having a higher rate of falling in the failure region since these samples contribute only to the evaluation of P_F . In this class of methods, the integral is written in the following form:

$$P_F = \int_{\Omega_X} I_F(\mathbf{x}) \frac{p(\mathbf{x})}{p_{IS}(\mathbf{x})} p_{IS}(\mathbf{x}) d\mathbf{x} = \mathbb{E} \left[I_F(\mathbf{X}) \frac{p(\mathbf{X})}{p_{IS}(\mathbf{X})} \right] \quad (30)$$

where $P_{IS}(\mathbf{x})$ is denoted the importance sampling density function to increase the probability of sampling from the failure region. Applying Monte Carlo simulation to the integral, P_F is then estimated by

$$P_F \cong \frac{1}{N_S} \sum_{k=1}^{N_S} I_F(\mathbf{x}_k) \frac{p(\mathbf{x}_k)}{p_{IS}(\mathbf{x}_k)} \quad (31)$$

The efficiency of this method relies on a proper choice of the importance sampling distribution, which inevitably requires some knowledge about failure zone. Many past studies successfully applied importance sampling to time-invariant reliability problems where the number of uncertain parameters is not too large (see, e.g., Schuëller and Stix 1987; Papadimitriou et al. 1997; Der Kiureghian and Dakessian 1998; Au and Beck 1999).

For instance, Schuëller and Stix (1987) proposed the selection of an importance sampling density function as an N -dimensional joint-normal PDF with uncorrelated components, where the mean value equals the design point as obtained from FORM analysis and standard deviation values corresponding to the standard deviations of the components of $\mathbf{X}$. Although design points are a good notion to characterize the important region in $\mathbf{X}$ and hence importance sampling densities centered on them are often a good choice, they are not a necessary ingredient for forming a good importance sampling density. Hence, adaptive or iterative schemes and in particular the kernel density estimators, which do not involve the notion of design points, have attracted

considerable attention (see Au and Beck (1999) for a complete discussion and suggestion of an efficient kernel method).

Au and Beck (2001b) have also developed a very efficient importance sampling method for the first-excursion problem for linear dynamical systems under Gaussian stochastic excitation. However, for time-dependent problems, which are often characterized by a large number of uncertain parameters with complexity arising from their dynamic nature, the application of importance sampling is much more difficult (Au and Beck 2003a).

Hence, Au and Beck (2001a) proposed a *subset simulation* technique that is capable of efficiently computing the small failure probabilities encountered in engineering reliability analysis of general dynamical systems.

Calculation of Failure Probability Using the Subset Simulation

Subset simulation is an efficient and adaptive stochastic simulation algorithm for estimating small failure probabilities in high dimensions (Au and Beck 2001a, 2003b; Zuev et al. 2012). The underlying idea is to express the small failure probability as a product of larger probabilities conditional on some intermediate events. This allows converting the simulation of a rare event into a sequence of simulations of more frequent events (see also Jalayer and Beck 2008; Jalayer et al. 2010).

In this methodology, the failure region is modeled as the last element in a sequence of embedded failure regions (i.e., decreasing nested sequence of failure regions) $F = F_m \subset \dots \subset F_2 \subset F_1$. F_1 is the first element in the failure sequence (i.e., largest failure region), and $F = F_m$ is the target failure region and the last element in the failure sequence. Therefore, by considering the product rule in probability, the failure probability can be derived as follows:

$$\begin{aligned} P_F &= P(F_m) = P(F_m|F_{m-1})P(F_{m-1}) \\ &= P(F_1) \prod_{i=1}^{m-1} P(F_{i+1}|F_i) \end{aligned} \quad (32)$$

According to Eq. 32, the rough idea of subset simulation is to estimate the failure probability as a product of a sequence of conditional probabilities denoted as $\{P(F_{i+1}|F_i): i = 1:m-1\}$ and $P(F_1)$. Hence, although P_F is small, the conditional probabilities can be made sufficiently large by appropriately adopting m .

Various simulation techniques can be used for sampling from PDFs conditional on a failure region F_i . Subset simulation proceeds in advance by simulating N_S samples $\mathbf{x}^{(0)}$ from $p(\mathbf{x})$ by MC simulation (note that superscript “0” denotes that the samples correspond to the first level):

$$P(F_1) = \int_{\Omega_x} I_{F_1}(\mathbf{x})p(\mathbf{x})d\mathbf{x} \cong \frac{1}{N_S} \sum_{k=1}^{N_S} I_{F_1}(\mathbf{x}_k^{(0)}) \quad (33)$$

From these samples, one can readily obtain new samples that are distributed as $p(\mathbf{x}|F_1)$ (i.e., these samples lie in F_1). These samples can be used to estimate $P(F_2|F_1)$ by sample averaging similar to what has already done in Eq. 33. These samples provide seeds for simulating more samples according to $p(\mathbf{x}|F_2)$ and hence for estimating $P(F_3|F_2)$. Repeating this process, the conditional probabilities of the higher-conditional levels can be computed until the failure region of interest F_m is attained. In the i th conditional level, where $1 \leq i \leq m-1$, let $\mathbf{x}^{(i)}$ be the samples with distribution $p(\mathbf{x}|F_i)$; the conditional probability can be expressed as

$$P(F_{i+1}|F_i) = \int_{\Omega_x} I_{F_{i+1}}(\mathbf{x})p(\mathbf{x}|F_i)d\mathbf{x} \cong \frac{1}{N_S} \sum_{k=1}^{N_S} I_{F_{i+1}}(\mathbf{x}_k^{(i)}) \quad (34)$$

The subset simulation is shown to be especially efficient for modeling rare failure events (i.e., when the probability of failure is very small). The statistical properties of each conditional failure probability as well as the P_F are derived in Au and Beck (2001a, 2003b).

Considering that the target failure region can be stated as $F = \{\mathbf{x}: D(\mathbf{x}) > C(\mathbf{x})\}$, the choice

of the sequence of embedded failure regions, F_i , is a key issue to be addressed. It can significantly affect the efficiency of the subset simulation procedure. If F is introduced with a single parameter, the sequence of intermediate failure regions F_i can be generated by adaptively varying that parameter. The (scalar) demand-to-capacity ratio, which is suitable within the structural reliability assessment, is defined as (Au and Beck 2003b; Jalayer et al. 2007a):

$$Y(\mathbf{x}) = \max_{j=1}^{N_{\text{mech}}} \min_{i=1}^{n_j} \frac{D_{i,j}(\mathbf{x})}{C_{i,j}(\mathbf{x})} \quad (35)$$

where N_{mech} is the number of potential failure mechanisms and n_j is the number of components in the j th mechanism (cf. Eq. 4). This generalized performance variable can be interpreted as the component demand-to-capacity ratio that brings the system closer to the desired limit state. It is interesting to note that the performance variable in Eq. 35 takes into account a range of potential failure mechanisms (*cut-sets*) as noted in section “[Structural Component and Structural System Reliability](#).” As a result, the target failure region can be rewritten as $F = \{\mathbf{x}: Y(\mathbf{x}) > 1\}$, and the sequence of embedded intermediate failure regions can be generated as $F_i = \{\mathbf{x}: Y(\mathbf{x}) > y_i\}$ where $0 < y_1 < \dots < y_m = 1$ are the intermediate thresholds. Au and Beck (2003b) proposed an adaptive methodology for choosing y_i values so that the estimated conditional probabilities are equal to a fixed value. They found that a fixed value equal to 0.1 yields good efficiency.

This section attempts to briefly introduce the main concepts of the subset simulation as an advanced stochastic simulation method for estimation of small probabilities corresponding to rare failure events. However, a detailed introductory description of methodology can be found in the chapter “[Subset Simulation Method for Rare Event Estimation: An Introduction](#)” of the general section “[Reliability and Robustness](#)” of the Encyclopedia of Earthquake Engineering.

Robust Reliability Assessment Using Simulation-Based Approaches

The characterization of uncertainties can be treated in two levels: (1) prior probability distributions for the uncertain parameters based on available information and/or (qualitative) professional judgment and (2) the results of in situ tests, various types of inspections, pseudo-dynamic health-monitoring tests, and the consideration of the corresponding measurement errors that can be used to update the prior distributions of uncertain parameters. The treatment of the latter issue is tackled by the Bayesian updating procedure (e.g., Box and Tiao 1973; Jaynes 2003).

In the *Bayesian* approach, the probability is always conditional on the amount of information available. In this probabilistic framework, probability represents the degree of belief in a certain outcome based on the amount of information. The Bayesian approach was not assessed objectively by many statisticians until late last century because of the absence of a strong rationale behind the theory (see Jaynes 2003; Zuev et al. 2012 for a brief summary of development corresponding to the Bayesian approach). However, the seminal work of the physicist Cox (1961) expounded by the physicist Jaynes (2003) has significantly enhanced the Bayesian probability theory as a convenient mathematical language for inference and uncertainty quantification. The Bayesian approach usually leads to high-dimensional integrals that often can be evaluated neither analytically nor numerically by straightforward quadrature. Nevertheless, the development of new algorithms as well as increasing computing power has led to an explosive growth of using Bayesian approach in different branches of science.

In the *robust* (updated) reliability approach, the plausibility of all the possible structural models conditional on the amount of information available is taken into account in a Bayesian framework (for more details, see Jaynes 2003; Papadimitriou et al. 2001; Beck and Au 2002; Jalayer et al. 2010; Zuev et al. 2012). The robust failure probability then can be calculated (in comparison to Eq. 21) by the following integral:

$$\begin{aligned} P_F &= p(F|D, M) = \int_{\Omega_{\mathbf{x}}} p(F|\mathbf{x}, D, M) p(\mathbf{x}|D, M) d\mathbf{x} \\ &= \int_{\Omega_{\mathbf{x}}} I_F(\mathbf{x}) p(\mathbf{x}|D, M) d\mathbf{x} \end{aligned} \quad (36)$$

where D denotes some test data and M is the set of possible structural models used to specify (both the structural and the probabilistic) modeling assumptions in the analysis; $p(\mathbf{x}|D, M)$ is the posterior PDF of the model parameters, $\mathbf{x}$, based on the observed data and assumed structural model; and $P(F|\mathbf{x}, D, M)$ is the failure probability given the model parameters defined by $\mathbf{x}$, which can be reduced to a deterministic index function, I_F . This index is a function of the model parameters which equals one if failure occurs and zero otherwise. The conditioning on M is included here to stress the fact that all probabilities involved in model updating are always conditional on the choice of the modeling assumptions.

The Bayesian framework is used herein to provide a rigorous method for updating the plausibility of each of the models in representing the structure that is quantified by the probability distribution over the vector of model parameters or the posterior PDF, $p(\mathbf{x}|D, M)$:

$$p(\mathbf{x}|D, M) = p_D(\mathbf{x}) = c^{-1} p(D|\mathbf{x}, M) p(\mathbf{x}|M) \quad (37)$$

where $p(\mathbf{x}|M)$ is the prior probability distribution for $\mathbf{x}$ specified by M , which reflects the relative plausibility of each model before utilizing the data D , $p(D|\mathbf{x}, M)$ is the (updated) probability distribution (also known as the likelihood function) for observed data D based on a model specified by the model parameters $\mathbf{x}$, and c^{-1} is a normalizing constant. Thus, the robust failure probability in Eq. 36 can be shown as

$$P_F = c^{-1} \int_{\Omega_{\mathbf{x}}} I_F(\mathbf{x}, M) p(D|\mathbf{x}, M) p(\mathbf{x}|M) d\mathbf{x} \quad (38)$$

Similarly, the general performance measure of Eq. 25 can also be rewritten based on the robust reliability concept as follows:

$$R_D = \int_{\Omega_{\mathbf{x}}} h(\mathbf{x})p(\mathbf{x}|D, M)d\mathbf{x} = \int_{\Omega_{\mathbf{x}}} h(\mathbf{x})p_D(\mathbf{x})d\mathbf{x} \quad (39)$$

Substituting Eq. 37 into 39, R_D can also be expressed as

$$R_D = c^{-1} \int_{\Omega_{\mathbf{x}}} h(\mathbf{x})p(D|\mathbf{x}, M)p(\mathbf{x}|M)d\mathbf{x} \quad (40)$$

Equations 36 and 38 (similarly, Eqs. 39 and 40) suggest two ways of evaluating the robust reliability by simulation. Equations 36 and 39 suggest estimating the P_F or R_D as the average of I_F or h over samples simulated from p_D , while Eqs. 38 and 40 indicate that the integral and the normalizing constant should be estimated, individually and then combined.

Particular difficulties are encountered in the evaluation of P_F or R_D based on the expressions in Eq. 36 or 39, respectively. The updated probability density function p_D is known only up to a multiplicative constant (see Eq. 37), since the normalizing constant c^{-1} is usually given by a high-dimensional integral that is also difficult to evaluate (Beck and Au 2002; Jalayer et al. 2010). Hence, the application of MC simulation or importance sampling is not generally feasible in this case, because these methods cannot simulate independent samples from p_D .

Additionally, when using importance sampling (see Eq. 30), it is necessary to choose a sampling density that is concentrated in the aforementioned small zone; otherwise similar problems, as in the MC simulation, will arise. However, this task is not trivial to accomplish since information about the zone, where $p(D|\mathbf{x}, M)$ is concentrated, is not directly available (see Beck and Au 2002 for more details). Strictly speaking, the posterior PDF p_D occupies a much smaller volume than that of the prior PDF $p(\mathbf{x}|M)$, so samples in its high probability region cannot

be generated efficiently by sampling from the prior PDF using direct MC method. Of course, if the posterior PDF p_D is evaluated first from Eq. 37, then there would be no problem in using the standard MC from Eq. 36. However, in this case, the factor c^{-1} needs to be calculated.

According to the drawbacks of the current MC methods as well as the importance sampling techniques in solving robust reliability problems, Markov chain Monte Carlo (MCMC) simulation techniques, in particular, the Metropolis-Hastings (MH) algorithm (Metropolis et al. 1953; Hastings 1970), are discussed briefly in the next section. It offers a feasible and powerful way for simulating samples according to an arbitrary distribution (when the target PDF is known only up to a scaling constant), at the expense of introducing dependence among the samples.

Generating Samples in Robust Reliability Based on Adaptive MCMC Simulation Technique

The goal of MCMC is to design a Markov chain such that the stationary distribution of the chain is exactly the distribution that we are interested in sampling from (i.e., the target distribution). The idea is to use specially designed methods for setting up the transition function, such that no matter how each chain is initialized, it will converge to the target distribution. The MH algorithm is normally used to generate samples according to an unscaled PDF when the target PDF is known only up to a scaling constant, i.e., there is no need to know the normalizing constant (see Eq. 33) in advance. The fact that this procedure allows us to sample from un-normalized distributions is one of its major attractions especially in case of Bayesian model updating. The MH algorithm was originally developed by Metropolis and his coworkers (Metropolis et al. 1953) in statistical physics and later generalized by Hastings (1970) in Bayesian statistics (see Fishman 1996 for comprehensive discussions on the MCMC methods). However, its potential use for solving reliability problems in structural engineering has been only recently demonstrated (see Au and Beck 1999, 2001a, 2003b; Beck and Au 2002).

The MH algorithm can be used to generate samples according to the target updated PDF p_D . Using the Markov chain samples generated from the MH procedure, P_F or R_D is estimated as the average over the samples, which is the same approach as the usual MC method, except that the samples are simulated from a Markov chain instead of being independent and identically distributed. In order to reduce the initial effect of the choice of the transient probability distributions (e.g., non-normalized target PDF) on the estimate, the first few samples are often not included in the sample averaging.

In the MH procedure, a proposal PDF is chosen to generate a candidate point that is conditional on the previous state of the sampler. The next step is to either accept the proposal or reject it. However, as noted previously, the updated posterior PDF p_D is concentrated in a small zone, and direct adaptation using a proposal PDF, which varies with a vastly different length scale from that of the target PDF, will not be effective (see Beck and Au 2002 for more details). Therefore, a sequence of intermediate proposal PDFs that vary gradually between the prior PDF and the target PDF p_D are introduced (Au and Beck 1999; Beck and Au 2002). According to the proposed methodology, however, the proposal PDF is chosen as the kernel sampling density constructed using the Markov chain samples from the previous simulation level (for the first simulation level, the prior PDF is used as the proposal PDF). Thus, the adaptation is done from one simulation level to the next. This methodology is especially useful in the subset simulation described previously in section “Calculation of Failure Probability Using the Subset Simulation.” Accordingly, a modified MH algorithm was developed by Au and Beck (2003b) that can obtain samples from a posterior PDF conditioned on a failure region F_i .

PEER Performance-Based Approach

In recent years, an effective foundation for the development of probabilistic Performance-Based Earthquake Engineering (PBEE) for the design

and assessment of building structures has been developed by the Pacific Earthquake Engineering Research Center (PEER; Cornell and Krawinkler 2000; Moehle and Deierlein 2004). There are several stages to this process: (1) calculation of ground motion hazard by quantifying uncertainty in ground motion with a probabilistic model for a parameter related to ground motion and known as the intensity measure (IM); (2) estimation of the uncertainty in structural response D (e.g., force and deformation engineering parameters), for each IM level; (3) estimation of the uncertainty in damage measure DM (i.e., physical states of damage) given response level D ; and (4) estimation of the uncertainty in the decision variable DV as the resulting consequences (e.g., financial losses, fatalities, and business interruption) given damage measure.

Each stage of the process is performed and executed (more or less) independently and then linked back together, as expressed in the following integral form:

$$\lambda(DV) = \iiint G[DV|DM] \cdot \left| \frac{dG[DM|D]}{dDM} \right| \cdot \left| \frac{dG[D|IM]}{dD} \right| \cdot \left| \frac{d\lambda(IM)}{dIM} \right| \cdot dIM \cdot dD \cdot dDM \quad (41)$$

where $G[Y|X]$ denotes generically the conditional Complementary Cumulative Distribution Function (CCDF) of Y given a certain value of X and $\lambda(Y)$ denotes the mean annual exceedance rate (mean annual frequency) of Y . As it can be observed from Eq. 41, the PEER framework enjoys a modular structure and benefits from the (hypothetical) conditional independence between the main parameters (i.e., the conditional independence of $DV|DM$ from D and IM and other ground motion parameters, $DM|D$ from IM and other ground motion parameters, and $D|IM$ from other ground motion parameters, such as, but not limited to, magnitude and distance).

This (hypothetic) Markovian independence between various intermediate parameters is one of the main factors that distinguish the PEER approach from the two other approaches

discussed in this entry, namely, the classic and the simulation-based reliability methods. In these approaches, the probability of failure (which can generically represent a decision variable DV exceeding a certain threshold value) is calculated directly and without considering intermediate parameters such DM , D , and IM . Another important factor that distinguishes the PEER framework equation (Eq. 41) from the other two approaches, discussed herein, is that Eq. 41 yields a rate of exceedance and not a probability. This is while the classic and the simulation-based reliability methods lead to a probability of exceedance. In other words, the rate of exceedance reported in Eq. 41 needs to be translated into probability by assuming an underlying probabilistic model (see Der Kiureghian 2005).

In this section, the second stage of the PEER integral expression dedicated to estimating the conditional probability of exceeding the engineering demand parameter D given IM , denoted as $G[D|IM]$, is discussed in detail. The estimation of the mean annual frequency of exceeding a specific IM values, denoted as $\lambda(IM)$, is the main focus of the chapter “► Probabilistic Seismic Hazard Models.” Finally, an outlook into the whole framework is provided in the chapter entitled “► Performance-Based Design Procedure for Structures with Magneto-Rheological Dampers”.

Taking into account other sources of uncertainty imposes an overall increase in the dispersion for the failure probability (Jalayer 2003; Jalayer and Cornell 2003), while an eventual shift in the median failure probability is not envisioned in this method (see the “hybrid” methods discussed in section “Alternative Methods Based on Time-Invariant Reliability Methods”).

In the PEER PBEE methodology, the evaluation of structural performance is defined by probabilistic performance objectives, which can be expressed in terms of the mean annual frequency (MAF) of exceeding a specified limit state (also referred to as the limit state frequency) denoted as λ_{LS} . Therefore, it is worth noting that the usual outcome of this framework is an estimate of the rate of exceeding a designated limit state threshold rather than a probability.

The main advantage of this methodology is that it evaluates the limit state frequency, λ_{LS} , by decoupling the ground motion hazard and nonlinear dynamic analyses via a site- and structure-specific intermediate variable known as the ground motion intensity measure, IM (see also Shome et al. 1998; Shome and Cornell 1999; Cornell and Krawinkler 2000; Luco 2002; Jalayer 2003; Jalayer and Cornell 2009). The ground motion IM serves as link between seismic hazard analysis, typically provided by seismologists, and structural analysis conducted by engineers.

This IM approach is appealing because it allows the first two analysis stages in the PEER PBEE methodology to be performed (almost) independently. The benefit of this approach is that the number of analyses needed can be substantially reduced because most of the uncertainties are concentrated in ground motion hazard in terms of the MAF of exceeding a certain level of IM , λ_{IM} , which can directly be estimated from probabilistic seismic hazard analysis (PSHA; Cornell 1968; McGuire 2004) for the area where the structure is located.

The conditional probability of D given IM can be predicted through alternative nonlinear dynamic analysis procedures. Herein, three distinct nonlinear dynamic procedures are described: (1) the so-called *cloud analysis* method, in which the structure is subjected to a set of (as-recorded) ground motions (Cornell et al. 2002; Jalayer and Cornell 2003; Elefante et al. 2010), and subsequently, the distribution of D given IM (D and IM are denoted as *cloud data*) is directly obtained by performing a logarithmic linear regression on the cloud data; (2) the incremental dynamic analysis (Vamvatsikos and Cornell 2004) where a selected suite of ground motions are incrementally scaled to different levels of the IM ; and (3) multiple-stripe analysis (MSA; Jalayer 2003; Jalayer and Cornell 2009), where analysis is performed at a specified set of IM levels known as *stripes*, each of which may be performed for a different suite of ground motions (i.e., structural dynamic analyses for multiple stripes of IM through selected set of records for each IM level). It is noteworthy that although IDA uses the same set of ground motions for all

IM levels, the MSA approach allows the re-selection of ground motions at each IM level to be consistent with the seismicity of the designated site (based on the disaggregation of seismic hazard; see, e.g., Baker and Cornell 2005). Thus, the distribution of D given IM is estimated for multiple IM levels.

The structural fragility curve for a range of IM values is a useful probabilistic structural response quantity that can directly be estimated from the aforementioned nonlinear dynamic analysis procedures. The structural fragility for a given limit state, LS , can be defined as the conditional probability of exceeding the limit state capacity for a given level of IM (Ellingwood 2001; Jalayer 2003; Baker and Cornell 2005; Jalayer and Cornell 2009; Baker 2014). If the considered limit state corresponds with the collapse condition, the associated fragility curve is known as the collapse capacity. Subsequently, this result can be combined with a ground motion hazard, i.e., λ_{IM} , to compute the MAF of exceeding any given limit state (Shome and Cornell 1999; Jalayer 2003; Jalayer and Cornell 2003; Ibarra and Krawinkler 2005; Haselton and Deierlein 2007).

Mean Annual Frequency of Exceeding a Limit State

The MAF of exceeding a specified limit state, denoted as λ_{LS} , can be obtained from two approaches: (a) the IM -based approach (also known as the fragility/hazard format) and (b) the D -based (i.e., demand-based) approach, which in the literature is also called the engineering demand parameter (EDP)-based approach (Cornell and Krawinkler 2000). The two approaches are expressed by the two following equations, respectively:

$$\lambda_{LS} = \int_{im} P[D > C_{LS} | IM = im] |d\lambda_{IM}(im)| \quad (42)$$

$$\lambda_{LS} = \int_{im} P[IM_{cap} < IM | IM = im] |d\lambda_{IM}(im)| \quad (43)$$

where C_{LS} is the capacity associated with the given LS , IM_{cap} is an uncertain parameter

Seismic Reliability Assessment, Alternative Methods for, Fig. 5 Typical fragility curve

representing the capacity of structure in terms of IM values (distribution of IM values) that result in a D level equal to C_{LS} , and the probability terms denote the structural fragilities for the desired limit state. The typical shape of the fragility curve is presented in Fig. 5.

The fragility curve can be estimated by cloud analysis, MSA, or IDA.

Cloud Analysis Approach

The probability term presented in Eq. 42 can be derived by assuming D to be a lognormal variable. This is a common assumption that has been confirmed as reasonable in many past studies (e.g., Porter et al. 2007; Jalayer and Cornell 2009):

$$P[D > C_{LS} | IM = im] = 1 - \Phi\left(\frac{\ln C_{LS} - \ln \eta_{D|IM}(im)}{\beta_{D|IM}(im)}\right) \quad (44)$$

where Φ is the standardized Gaussian CDF and η and β are conditional median and standard deviation (dispersion) of the natural logarithm of D given IM . In order to estimate the statistical properties of the cloud data, i.e., conditional median and dispersion, conventional linear regression (using least squares method) is used in the natural logarithmic scale, as shown in Fig. 6. Thus,

Seismic Reliability Assessment, Alternative Methods for,
Fig. 6 Typical logarithmic linear regression on cloud data

$$\ln \eta_{D|IM}(im) = \ln a + b \ln(im),$$

$$\beta_{D|M} = \sqrt{\frac{\sum_{j=1}^{N_{\text{cloud}}} \left(\ln \frac{C_{LS}}{a \cdot im_j^b} \right)^2}{N_{\text{cloud}} - 2}} \quad (45)$$

where a and b are the coefficients of the logarithmic linear regression and N_{cloud} is the number of the cloud data.

Rare events may exert a very large demand D (i.e., even cause instability in the nonlinear dynamic analysis) that can affect the general trend in the linear regression of the cloud data. In such cases, a logistic regression (Agresti 2002) can generally be used. In this methodology, binary values of 0 (for non-collapse data) and 1 (for collapse cases) are assigned for each IM , and the logistic regression allows the construction of the associated fragility curve based on these binary data (Baker and Cornell 2005; Elefante et al. 2010).

IDA Approach

In a great number of research works (see, e.g., Jalayer 2003; Vamvatsikos and Cornell 2004; Baker and Cornell 2005; Ibarra and Krawinkler 2005; Zareian and Krawinkler 2007; Haselton and Deierlein 2007; Jalayer and Cornell 2009; Baker 2014), the collapse capacity is estimated by repeatedly scaling a ground motion using the IDA procedure until the ground motion causes collapse of the structure; hence, each ground motion can be associated with a single IM value

Seismic Reliability Assessment, Alternative Methods for,
Fig. 7 Typical IDA curves and fitting of the empirical distribution of the IM related to the overcoming of limit state

associated with collapse. By repeating this process for a set of ground motions, one can obtain a set of IM values corresponding to the onset of collapse. Subsequently, the probability of collapse for a specific IM equal to im can be estimated as the fraction of records for which collapse occurs at a level lower than the predefined value, im . A lognormal distribution is often fitted to the empirical distribution of IM levels that cause the structure to collapse. In Fig. 7, the black dashed line represents the LS threshold, and the red stars illustrate the

IM_{cap} values that cause the onset of the limit state. On the same diagram, the histogram of the IM_{cap} data and the related empirical distribution are shown as well.

Multiple-Stripe Analysis Approach

In cases where different records are used at each IM level, the IDA method (section “[IDA Approach](#)”) cannot be used to estimate the probability of collapse. A substitute for the conventional IDA approach should be utilized in this particular case. Therefore, instead of an IM value associated with the onset of collapse for each record (i.e., the IDA approach), the fraction of records that cause collapse at each IM level can be taken into account. The latter can be obtained from individual stripes by calculating the number of accelerograms for which the limit state has been exceeded with respect to the total number of records (Baker and Cornell 2005; Ebrahimian 2012; Baker 2014).

As a result, the empirical distribution of the collapse capacity for a set of IM values can be obtained. Once the ratio of the number of collapse cases to the total number of ground motions is calculated for each IM level, a fragility curve can be generated through the logistic regression. The observed fraction of collapse and the estimated

fragility function are shown schematically in Fig. 8 (Ebrahimian 2012).

Demand and Capacity Factor Design (DCFD) Format (IM-Based Version)

The IM -based closed-form solution for the annual frequency of exceeding a desired limit state, λ_{LS} , has been derived by Jalayer (2003) (see also Jalayer and Cornell 2003) under a set of simplifying assumptions. It is used as a performance-oriented design procedure proposed in the SAC/FEMA Steel Project (Cornell et al. 2002) as

$$\lambda_{LS} = \lambda_{IM}(\eta_{IMcap}) \exp\left(\frac{1}{2}k^2\beta_{IMcap}^2\right) \quad (46)$$

where η_{IMcap} and β_{IMcap} are the parameters of the estimated lognormal distribution assuming that the IM_{cap} capacity is a lognormal variable and k reflects the steepness of the hazard curve, λ_{IM} , in the vicinity of the point η_{IMcap} (the hazard curve is approximated in the region of interest by the power-law relationship as $\lambda_{IM}(\eta_{IMcap}) = k_0(\eta_{IMcap})^{-k}$). The first term in Eq. 46 shows the first-order approximation to the limit state probability, and the exponential expression is a magnifying factor that accounts for the

Seismic Reliability Assessment, Alternative Methods for, Fig. 8 (a) Typical MSA output and (b) fragility curve obtained through the logistic regression applied on the MSA results

sensitivity of the limit state probability to the randomness in the IM_{cap} .

The closed-form expression for the limit state frequency can represent an alternative interpretation for the seismic design or assessment considering an IM -based design criterion. A certain design criterion is to check whether the MAF of exceeding a certain limit state (limit state frequency) is less than or equal to an allowable annual frequency, λ_o . Thus,

$$\lambda_{LS} = \lambda_{IM}(\eta_{IM_{cap}}) \exp\left(\frac{1}{2}k^2\beta_{IM_{cap}}^2\right) \leq \lambda_o \quad (47)$$

After some simple rearrangements with the objective of allocating the parameters corresponding to the capacity to one side, Eq. 47 takes the following form (Jalayer 2003; Jalayer and Cornell 2003):

$$im^{\lambda_o} \leq \eta_{IM_{cap}} \exp\left(-\frac{1}{2}k^2\beta_{IM_{cap}}^2\right) \quad (48)$$

where im^{λ_o} is the indicator IM for a hazard level equal to the allowable annual frequency, λ_o . The right-hand side of this expression represents the *factored capacity* (expressed in terms of the adopted IM). Therefore, this expression illustrates a design criterion based on the fragility/hazard format in terms of the IM -based factored capacity being greater than or equal to the IM for a given allowable annual rate.

Summary and Future Challenges

A summary of general methodologies used in the seismic reliability assessment has been presented. In particular, the historical evolution of each method that allows for accounting uncertainties in demand and capacity is briefly illustrated. It is noted that considerable progress has been made in the development of these methodologies, and great efforts have been performed to implement them with the aim of loss reduction and risk mitigation. Considering that the seismic reliability of structures is a specific time-dependent problem with many sources of

uncertainty, applying any of the aforementioned methods is not a trivial task.

Arguably, the first-order and second-order reliability methods cannot be adopted in a straightforward manner when solving time-dependent nonlinear reliability problems. On the other hand, the PEER approach works best in cases where the primary source of uncertainty is reflected in the RTR variability (Der Kiureghian 2005). Therefore, in the recent years, various hybrid methods (section “[Alternative Methods Based on Time-Invariant Reliability Methods](#)”) have been proposed (see, e.g., Liel et al. 2009). Other approaches include those developed by Vamvatsikos and Fragiadakis (2010) and Celarec and Dolšek (2013) where the PEER approach is mixed with other reliability methods (FOSM and Latin hypercube sampling). As a result, the treatment of various sources of uncertainty in both aforementioned reliability methods deserves further research and investigations.

It is noteworthy that both the modern construction codes and the professional community of engineers around the world are becoming more inclined towards the application of nonlinear dynamic analyses. This raises the professional interests to the PEER approach, since it provides a more accessible way of taking into account and propagating the RTR variability in design and assessment problems. Moreover, this approach leads directly to the estimation of the economic losses, which are viewed as essential risk metrics in decision making.

In order to take into account various sources of uncertainty (e.g., modeling, RTR, etc.) in the PEER approach while maintaining a low number of structural analyses, Jalayer et al. (2013) proposed a method inspired from the concept of robust reliability discussed in section “[Calculation of Failure Probability Using the Subset Simulation](#).” Conditioned on a prescribed analytical fragility model, they suggest using the standard MC simulation (with few samples) in order to create various structural model realizations based on the modeling uncertainties present in the problem. A suite of recorded ground motions employed to represent the RTR variability is then applied to each of the above-mentioned structural

models in order to calculate a desired structural response. In other words, the number of structural response realizations is equal to the number of ground motion records present in the suite of records. These structural response realizations are then used as data in order to both update the joint probability distribution for the parameters of the adopted analytic fragility model and also to directly obtain the robust fragility.

In the simulation-based approach, consideration of RTR variability requires the adoption of a suitable stochastic ground motion model (see the chapter “► [Stochastic Ground Motion Simulation](#)”) conditional on seismic source parameters (see Au and Beck 2003b; Jalayer and Beck 2008). Accordingly, the consideration of RTR variability together with other sources of uncertainties will provide a complete probabilistic treatment of the structural response (see, e.g., Jalayer et al. 2007b where RTR variability and modeling uncertainty are considered together in the seismic reliability analysis of RC frames based on the subset simulation). One of the main challenges in applying this approach is to ensure that the stochastic ground motion model provides a realistic description of the characteristics of the ground motions expected to happen at the building site (see, e.g., Atkinson and Silva 2000; Rezaeian and Der Kiureghian 2010). Moreover, there are difficulties in the application of advanced simulation-based algorithms (e.g., subset simulation) so that these techniques cannot be performed in a straightforward and practical manner. However, the fast and incredible increase in computational power is going to render the simulation-based methods ever more accessible for resolving high-dimensional reliability problems.

In comparison to the PEER approach, the advanced simulation-based methods have the advantage of being able to directly estimate losses without passing through multiple stages (e.g., hazard, demand, damage, losses). Undoubtedly, the application of advanced simulation-based techniques is another major concern in the future of reliability methods due to the usually high dimension of the vector of uncertain parameters.

The Bayesian network methodologies have been developed during the past 25 years mostly in the field of artificial intelligence (Russell and Norvig 2003). This method has recently been applied in order to solve high-dimensional structural reliability problems such as infrastructure seismic risk assessment for spatially distributed systems (see, e.g., Grêt-Regamey and Straub 2006; Straub and Der Kiureghian 2010). The Bayesian networks rely on graphical visualization of the uncertain parameters and their correlation structure. They are arguably going to become efficient means of resolving systemic reliability problems due to their propensity for being automatized and also due to the fact that they lend themselves quite well to the implementation of advanced simulation-based methods.

Synonyms

City resilience; Community resilience; Disaster resilience; Ecosystem resilience; Engineering resilience; Urban resilience

Introduction

Resilience has several meanings in academic discourse. It is derived from the Latin term *resilire*, which means “to bounce back.” It is used in multiple scientific contexts to identify the capability to recover, absorb shocks, and restore equilibrium after a perturbation. First, the concept of resilience was introduced in the nineteenth century in physics to indicate the ability of materials to withstand impulsive loads without suffering damages. Then, resilience was also used in medicine (Pfeiffer 1929) and psychology (Werner 1971; Garmezy 1973).

Recently, resilience is triggering increasing interest in other scientific contexts, referred to communities, urban systems, and built environment, as the capability to recover from natural and human-induced disasters. The advent of the concept of resilience in this context is the result of an increasing need for a response to new and intense threats to modern societies. Increasing interdependence and complexity of contemporary cities along with more severe events induced by climate change is making modern societies ask for prevention, preparation, reduced impacts and damages, and rapid recovery; that is resilience. This urgent need is pushing scientific community to discuss about the best approach to resilience against disasters and, first of all, to define disaster resilience (see “► [Earthquake Disaster Recovery: Leadership and Governance](#)”;

“► [Earthquakes and Their Socio-economic Consequences](#)”).

Contemporary cities can be interpreted as complex systems, composed of dynamic relationships between physical environment, i.e., infrastructural systems (e.g., utility and transportation networks) and more in general all lifelines, natural environment and social environment, consisting of communities and their internal relationships. Hence, according to a general definition, cities can be considered resilient if able to cope with extreme events without suffering devastating losses and damages to their physical systems or reduced quality of life for the inhabitants (Godschalk 2003). However, a comprehensive definition is still not available, given the complexity in defining the properties of urban systems and the response of cities to extreme events.

What are the real operations taking place in urban systems? What about the dynamic equilibrium at the basis of the urban system operations? What is meant by limited damages and preservation of functionality for urban systems after extreme events? Does the optimal response of urban systems to extreme events, i.e., the “resilient” response, depend on the type of extreme event? These are just some of the questions that make the concept of resilience exploding with different and multidisciplinary meanings.

Defining Resilience

The extreme events that urban systems can be subjected into can be divided into four categories (O’Brien et al. 2006), and each of them may need different approaches to define a resilient response:

- Natural events, such as earthquakes, tsunamis, floods, etc.
- Technological events, or human-induced events, such as accidents on transport networks, industrial accidents, terrorist attacks, etc. In developed countries, these events are extensively considered in risk management strategies, aimed at public awareness of risks,

risk mitigation, and building capacity to withstand and recover from extreme events.

- Humanitarian emergencies, i.e., man-made or natural events, hitting very vulnerable and weak populations, such as droughts, famines, epidemics, wars, etc.
- Events induced by climate changes, i.e., events that may still be counted as natural events (floods, landslides, etc.) or as humanitarian emergencies (drought, heat waves, etc.) but that are induced by recent climate changes and can affect unprepared populations with unexpected intensity. In addition, for the climate-induced events, the most effective mitigation techniques are indirect, undertaken on a global scale, through the reduction of greenhouse gases.

Hence, resilience of urban systems against different events varies, and different strategies can be implemented to build resilient cities, in terms of risk mitigation actions, shock preparedness, and recovery capability from damages.

Given the multiplicity of points of view to disaster resilience, numerous definitions of resilience are available in literature; an excellent review of these definitions is presented by Zhou and coworkers (Zhou et al. 2010), who elaborated the most of the following list:

- Holling (1973, 1986), Holling et al. (1995)

Resilience is defined as the amount of disturbance that can be sustained by a system before a change in system control or structure occurs. It could be measured by the magnitude of disturbance the system can tolerate, still persisting in its pre-disturbance state

- Timmerman (1981)

Resilience is the ability of human communities to withstand external shocks or perturbations to their infrastructure and to recover from such perturbations

- Pimm (1984)

Resilience is the speed with which a system returns to its original state following a perturbation

- Pimm (1984), Holling et al. (1995), Gunderson et al. (1997)

Resilience of an ecological system relates to the functioning of the system, rather than the stability

of its component populations, or even the ability to maintain a steady ecological state

- Wildavsky (1991)

Resilience is the capacity to cope with unanticipated dangers after they have become manifest, learning to bounce back

- Dovers and Handmer (1992)

Re-active and pro-active resilience of society can be distinguished, based on the major difference between ecosystems (that react to disturbances) and societies (that can plan in advance, due to human capacity for anticipation and learning)

- Adger (1997, 2000)

Social resilience could be measured through proxies of institutional change and economic structure, property rights, access to resources, and demographic change

- Horne and Orr (1998)

Resilience is a fundamental quality of individuals, groups and organizations, and systems as a whole to respond productively to significant change that disrupts the expected pattern of events without engaging in an extended period of regressive behavior

- Mallak (1998)

Resilience is the ability of an individual or organization to expeditiously design and implement positive adaptive behaviors matched to the immediate situation, while enduring minimal stress

- Milette (1999)

Local resiliency with regard to disasters means that a locale is able to withstand an extreme natural event without suffering devastating losses, damage, diminished productivity or quality of life and without a large amount of assistance from outside the community

- Comfort (1999)

The capacity to adapt existing resources and skills to new systems and operating conditions

- Milette (1999), Geis (2000), Chen et al. (2008)

In the context of disaster management, resilience is used to describe the ability to resist or adapt to stress from hazards, and the ability to recover quickly

- Adger (2000), Kimhi and Shamai (2004)

Social resilience is understood as having three properties: resistance, recovery and creativity, in which (1) resistance relates to a social entity's efforts to withstand a disturbance and its consequences, and can be understood in terms of the degree of disruption that can be accommodated without social entity undergoing long-term change; (2) Recovery relates to an entity's ability to pull through the disturbance, and can be understood in terms of the time taken for an entity to recover from a disruption. (3) Creativity is represented by a gain in resilience achieved as part of the recovery process, and it can be attained by adapting to new circumstances and learning from the disturbance experience

- Carpenter et al. (2001)

The Resilience Alliance consistently refers to social-ecological systems (SES) and defines their resilience by considering three distinct dimensions: (1) the amount of disturbance a system can absorb and still remain within the same state or domain of attraction; (2) the degree to which the system is capable of self-organization; (3) the degree to which the system can build and increase the capacity for learning and adaptation

- Paton et al. (2000)

Resilience describes an active process of self-righting, learned resourcefulness and growth—the ability to function psychologically at a level far greater than expected given the individual's capabilities and previous experiences

- UN/ISDR (2009)

The ability of a system, community or society exposed to hazards to resist, absorb, accommodate to and recover from the effects of a hazard in a timely and efficient manner, including through the preservation and restoration of its essential basic structures and functions. Resilience means the ability to “resile from” or “spring back from” a shock. The resilience of a community in respect to potential hazard events is determined by the degree to which the community has the necessary resources and is capable of organizing itself both prior to and during times of need.

- Bruneau et al. (2003)

An analysis of seismic resilience at four levels: (1) technical, how physical systems perform when subjected to earthquake forces; (2) organizational, the ability to respond to emergencies and carry out critical functions; (3) social, the capacity to reduce the negative social consequences of loss of critical

services; and (4) economic, the capacity to reduce both direct and indirect economic losses. Resilience has four dimensions: (1) robustness, strength to withstand a given level of stress without loss of function; (2) redundancy, the extent to which elements and systems are substitutable; (3) resourcefulness, the capacity to identify problems, establish priorities and mobilize resources; and (4) rapidity, the capacity to meet priorities and achieve goals in a timely manner. A resilient system has: (1) reduced probability of failures; (2) reduced consequences from failures; and (3) reduced time to recovery

- Kendra and Wachtendorf (2003)

The ability to respond to singular or unique events

- Cardona (2003)

The capacity of the damaged ecosystem or community to absorb negative impacts and recover from these

- Pelling (2003)

The ability of an actor to cope with or adapt to hazard stress

- Rockstrom (2003)

Strategies of social resilience building include manageable strategies, such as institutional development, land reform, land tenure, diversification, marketing, human capacity building, and unmanageable ones, such as relief food, cereal banks, social networks, virtual water imports

- Rose (2004, 2007)

Resilience includes inherent resilience (ability under normal circumstances) and adaptive resilience (ability in crisis situations due to ingenuity or extra effort)

- Aguirre (2006)

A resilient social entity absorbs, responds and recovers from the shock; and improvises and innovates in response to disturbances

- Maguire and Hagan (2007)

In broad terms, social resilience is the capacity of a social entity (e.g., a group or community) to bounce back or respond positively to adversity

- Kang et al. (2007)

Resilience is the ability of the system to recover once hazard has occurred and can be measured by the duration of an unsatisfactory condition.

- Asprone and Manfredi (2014)

An extreme event and the resulting changes, moving urban systems to new dynamic equilibrium, represent a phase in urban life cycle; resilience represents the sustainability of this phase, from the economic, social and environmental point of view, for all the present and future actors, directly and indirectly involved in the recovery process.

Resilience of Ecosystems and Engineering Resilience

To apply the concept of resilience to complex systems, such as cities, two approaches can be followed: the resilience of ecosystems (a) and the engineering resilience (b). In the first, proposed and developed by Holling (1973, 1986, 2001), resilience can be defined as the ability of a system in dynamic equilibrium, subject to external shocks, to move back to a dynamic equilibrium state. On the contrary, engineering resilience, developed by Pimm and other authors (Pimm 1984; Bruneau et al. 2003) can be defined as the ability of a system to absorb an external shock and quickly return to the initial state.

Apparently the first definition may be more complete and suitable for urban systems; in fact, moving from the fact that a complex system in dynamic equilibrium (as the urban system, which consists of physical and social subsystems linked by a dynamic network of relationships) can present different equilibrium states (i.e., can “work”) in various configurations, it can be concluded that a positive response to a negative external shock can be also represented by a new equilibrium state, different from the previous one. For example, looking at the terrorist attack on the World Trade Center in New York on 11 September 2001, it can be said that the city of New York had a “resilient” response. New York quickly recovered from the social and economic effects induced by the event, even if a new equilibrium was reached in a different configuration of the physical system, i.e., without rebuilding the World Trade Center towers and relocating the activities that took place there, that is, re-thinking that space (i.e., “ground zero” site).

Furthermore, the social value of the towers, representing a crucial symbol for the collective identity of the city of New York, has been preserved by reconfiguring the city in a different dynamic equilibrium. The towers’ values still exist and their physical absence was recovered from the social and cultural point of view. Nevertheless, engineering resilience is also extremely meaningful. In fact, one could argue that a complex and dynamic system, as the city, is always able to reach a state of equilibrium after a shock, because the ability of cities to adapt to changes is extremely high. But the new post-event dynamic equilibrium could be “worse” than the previous one. In this case only with an engineering resilience approach a “negative” response can be appreciated; for example, quality and performance indicators of the urban system can be used for this scope. Hence, aiming at synthesizing the different approaches, it can be concluded that the urban system is resilient if, after a shock, it can reach a dynamic equilibrium state, even if different from the previous one, but the urban system is really resilient if, at the same time, certain indicators of quality and performance of the system return to pre-shock values. This concept was also introduced by Dalziel and McManus (2004), which affirmed the need to introduce metrics of resilience. Hence, the questions the scientific community is currently dealing with refer to the indicator system that should be used. Are the indicators currently in use to assess city sustainability suitable for the scope? Which quality and performance indices can describe the “effectiveness” of the response to external shocks?

A further approach to the concept of resilience of cities leads to the definition of the social resilience. It moves from the centrality of communities in urban systems, i.e., the predominance of the social over the physical system; according to this approach, social resilience is defined as the ability of communities to deal with external shocks, managing the changes induced on infrastructures, on the external environment, and on the economic and social systems (Adger 1997, 2000). Social resilience, according to Adger, can be measured by three characteristics: resistance

to external shocks (a), the ability to recover from external shocks (b), and creativity (c), that is, the ability to adapt to new circumstances (Adger 2000; Kimhi and Shamai 2004). With a similar approach, Lorenz (2010) affirms that social resilience consists of the adaptive capacity (a), that is, the ability to change in order to withstand the external shocks; the coping capacity (b), that is, the ability to preserve and give continuity to the system of relationships, given the external shocks; and the participative capacity (c), that is, the self-organization ability, aimed at coping with external shocks. Hence, the approach to social resilience affirms the centrality of communities, able to manage the other physical elements and determine resilient urban systems.

In all the approaches so far analyzed, however, resilience is perceived as the ability of the city to have a “positive” response, when exposed to an external shock, as an extreme event. The main issue is the need to define a “positive” response: the ability to return to the previous equilibrium configuration or even a different reconfigured equilibrium state. And, in a complex and dynamic system, what is an equilibrium state? Furthermore, is resilience to be reached separately both in the social and the physical systems, or does social system resilience entail physical system resilience? Thus, is the physical system resilience condensed in community resilience? Hence, is community, representing the only decision maker for urban management, the only master of a city’s destiny, the key to a resilient city?

Quantifying Resilience

The increasing interest in resilience requires methodological frameworks to measure and assess it. Measuring disaster resilience would help understand and improve resilience of urban systems against risks and implement the most effective strategies to “bounce back” from disasters. Aimed at this goal, different studies have been developed, proposing measurement frameworks of disaster resilience and other properties related to resilience.

The most important methodologies available in literature can be divided into two categories: (a) the physical resilience approach and (b) the social-economic resilience approach. In the former, attention is focused on performances of physical systems, e.g., single structures, urban lifelines, and transportation systems. In this case, resilience is measured as the capability of the physical components and systems to recover their functionality. Mainly, these methods are developed and proposed within engineering community. In the latter, attention is focused on social systems, and resilience is measured as the capability of communities to recover a good life quality level. Mainly, these methods are proposed in social sciences community.

Physical Resilience

Bruneau et al. (2003) define resilience as characterized by four main properties: robustness, rapidity, redundancy, and resourcefulness (4 R’s), to be managed and computed as proxies of resilience. *Robustness* is related to the “strength, or the ability of elements, systems, and other units of analysis to withstand a given level of stress or demand without suffering degradation or loss of function.” *Rapidity* is “the capacity to meet priorities and achieve goals in a timely manner in order to contain losses and avoid future disruption.” *Redundancy* refers to the availability of substitutable elements or systems in the aftermath of a disruption, and *resourcefulness* is the capacity to mobilize material and human resources. Within this approach, different methods have been proposed, whose final scope is to compute resilience as the ability to cope with degradation in system performance $Q(t)$, over time. Numerically, resilience R is often computed as the area underneath function $Q(t)$, divided by the time to restore the pre-event performance (Fig. 1):

$$R = \frac{\int_{t_0}^{t_1} Q(t) dt}{t_1 - t_0} \quad (1)$$

Seismic Resilience, Fig. 1 Physical resilience

Being t_0 the time of the event and t_1 the time of the total recovery of the pre-event performance. This approach has been applied to buildings (Bruneau and Reinhorn 2007), bridges (Decò et al. 2013), road networks (Arcidiacono et al. 2012), and urban infrastructure systems (Ouyang and Dueñas-Osorio 2012; Franchin and Cavalieri 2013), using different performance functions $Q(t)$.

Further works are increasingly conducted on this topic and made available in literature, focusing on different urban systems and different performance functions $Q(t)$; however, the most of the works in recent literature share the theoretical scheme in Eq. 1 to compute resilience. Recently, Cavallaro et al. (2014) and Franchin and Cavalieri (2013) applied this approach to social-physical graphs (merging physical networks and social components) using as performance $Q(t)$ the efficiency of the network in the “social” nodes, aiming at measuring the capability of the physical systems to serve their end users.

Social-Economic Resilience

Studies aimed at computing resilience from a social perspective focus on economic, demographic, and institutional variables, in time and space. In example, economic growth and the

distribution of income among people are fundamental aspects of resilience (Adger 2000) and are often used to compute resilience. Attitude to mobility and migration or amount of young people is also related to resilience (Ruitenbeek 1996; Adger 2000). Social memory of past changes and impacts (Olick and Robbins 1998) also relates to the capacity of communities to adapt and cope with disasters, that is, resilience. Hence, different authors refer to this kind of variables to estimate community resilience, in terms of preparedness and coping capacity to disasters. Specific indicators have been also developed, moving from social-economic variable. This is the case of the Disaster Deficit Index (DDI), proposed by Cardona et al. (2008), measuring country resilience against disasters from a macroeconomic perspective:

$$DDI = \frac{L_R}{R_E} \quad (2)$$

being L_R the maximum expected direct economic impact of possible disasters and R_E the available internal and external resources that can be made available to face disasters.

A recent attempt to integrate physical and social-economic perspectives of resilience has been done with the PEOPLES Resilience Framework (Renschler et al. 2010), linking different resilience dimensions (technical, organizational, societal, and economic) and resilience properties (robustness, redundancy, resourcefulness, and rapidity) as proposed by Bruneau et al. (2003).

Summary

An increasing research interest in scientific community is focusing on disaster resilience of urban environment, from different scientific perspectives, including those from risk engineering and social sciences communities. A comprehensive approach to resilience is still not available, but the need for a general methodology to manage and measure urban resilience is urged due to the

increasing interdependence and complexity of contemporary cities along with more severe events induced by climate change.

This entry deals with the most recent approaches to urban disaster resilience. It moves from the description of a large variety of definitions of disaster resilience, as proposed by researchers of different disciplines. The differences between engineering resilience and resilience of ecosystems are discussed. Thus, different approaches to compute and measure resilience are described, focusing on physical resilience, i.e., resilience of infrastructures and lifelines, and social-economic resilience, i.e., resilience of social systems and communities.

Introduction

All structures degrade when acted upon by cyclic forces such as those associated with earthquakes, high winds, and sea waves. Development of a practical model of degrading structures that would match experimental observations is an important task. Furthermore, identification and prediction of deterioration is a problem of considerable practical significance. Under cyclic excitation, degradation manifests itself in the evolution of the associated hysteresis loops. Theoretical research in internal friction in the last few decades has noticeably increased the conceptual understanding of hysteresis (Kojic and Bathe 2005; Krasnoselskii and Pokrovskii 1989). Practical issues related to internal friction, however, have not been adequately addressed. The lack of a practical theory of hysteretic evolution is at present a major barrier to successful design of structures against performance deterioration.

In the past 30 years, cyclic performance testing of structural joints and subassemblies around the world has generated a substantial amount of experimental data on load–displacement traces. In the same period, the generalization of the Bouc–Wen differential model of hysteresis permits curve fitting of practically any hysteretic trace with a suitable choice of its 13 control parameters (Bouc 1967; Wen 1976). Using system identification techniques, it appears highly feasible to utilize the generalized differential model of hysteresis and the extensive database of experimental hysteretic traces to deduce a working model for degrading structures. A fundamental objective of this research project is to do just that.

Many questions naturally spring to mind. What are the advantages of the differential model over other empirical models of hysteresis? How can an empirical model of hysteresis be used for prediction of nonlinear system response? What are the factors that would affect the precision of prediction? These questions will be answered along the way. Two principal tasks in connection with hysteretic evolution will be addressed. First, a robust identification algorithm will be used to generate

hysteretic models of a deteriorating structure from its experimental load–displacement traces. Second, it will be shown that a hysteretic model obtained by system identification can be used to predict the future performance of the same deteriorating structure. The organization of this entry is as follows. In section “[Differential Model of Hysteresis](#),” the smoothly varying Bouc–Wen differential model of hysteresis in both its classical (non-degrading) and generalized forms is described. A robust identification algorithm is constructed in section “[System Identification](#)” to generate hysteretic models of a deteriorating structure from its experimental load–displacement traces. This algorithm is based upon the generalized Bouc–Wen model and differential evolution, streamlined through global sensitivity analysis. The model thus generated can account for degradation and pinching effects, which are prominent features of real-life structural deformation. To obtain experimental data for model validation, cyclic performance tests of simple joints and subassemblies are reported in section “[Prediction of Performance](#).” Using an experimental load–displacement trace, a working hysteretic model is identified. It will be shown that the hysteretic model obtained by identification may be used for predicting the nonlinear response of the same structure when driven by other cyclic loads. Finally, the requirements for accurate prediction of system response will be discussed. The terms “Bouc–Wen model” and “differential model” will be used interchangeably throughout the entry.

Differential Model of Hysteresis

When a structure is subjected to severe cyclic loading, the hysteresis loops associated with the structural response are memory dependent. That means the evolution of hysteresis loops depends not only on the instantaneous deformation but also on the history of deformation. This memory nature of degradation makes modeling and analysis challenging. The generalized Bouc–Wen model is one of the widely used empirical models capable of modeling the memory effects.

Suppose the equation of motion of a multi-degree-of-freedom system can be decoupled and, along the direction of the generalized coordinate x , the system is governed by

$$m\ddot{x} + c\dot{x} + r(x, z) = f(t) \quad (1)$$

where m and c are, respectively, the mass and damping coefficients, z is an imaginary hysteretic displacement, and $r(x, z)$ is the total restoring force. It is assumed that the excitation $f(t)$ is cyclic. In the development of differential model, the restoring force $r(x, z)$ is separated into an elastic (linear) component and a hysteretic (nonlinear) component by

$$r(x, z) = \alpha kx + (1 - \alpha)kz \quad (2)$$

where k is the stiffness coefficient and $0 \leq \alpha \leq 1$ is a weighting parameter. Obviously, the restoring force is purely hysteretic if $\alpha = 0$; it is purely elastic if $\alpha = 1$. A diagrammatic representation of the system is shown in Fig. 1.

Hysteresis loops may be generated if the hysteretic displacement z and the total displacement x are connected by the nonlinear differential equation (Bouc 1967; Wen 1976)

$$\dot{z} = A\dot{x} - \beta|\dot{x}||z|^{n-1}z - \gamma\dot{x}|z|^n \quad (3)$$

There are five unspecified loop parameters A , α , β , γ , and n in Eqs. 2 and 3, which together represent the classical Bouc–Wen model. The parameters A , β , and γ are basic hysteresis shape parameters. The parameter n controls the sharpness of yield. Over the years, the original Bouc–Wen model has been extended, and new parameters have been added to fit hysteretic shapes arising from deteriorating systems. The result is a contemporary model with thirteen control parameters given by

$$\dot{z} = h(z) \left\{ \frac{A\dot{x} - v \left(\beta|\dot{x}||z|^{n-1}z + \gamma\dot{x}|z|^n \right)}{\eta} \right\} \quad (4)$$

In the above expression, v and η are degradation shape functions (Baber and Wen 1981), and $h(z)$

Seismic Response Prediction of Degrading Structures, Fig. 1 Schematic diagram of a hysteretic degrading system

is a pinching shape function. In general, degradation depends on the response duration and severity. A convenient measure of such combined effect is the energy

$$E(t) = \int_0^t (1 - \alpha)kz\dot{x}dt \quad (5)$$

dissipated through hysteresis from initial time $t = 0$ to present time t . Since

$$\varepsilon(t) = \int_0^t z \dot{x}dt \quad (6)$$

is proportional to $E(t)$, it may also be used as a measure of response duration and severity. Both degradation shape functions v and η are assumed to depend linearly on ε as the system evolves:

$$v(\varepsilon) = 1 + \delta_v \varepsilon \quad (7)$$

$$\eta(\varepsilon) = 1 + \delta_\eta \varepsilon \quad (8)$$

Two unspecified degradation parameters δ_v and δ_η are thus introduced. Under cyclic excitation, the pinching of hysteresis loops is often observed.

For example, pinching may be associated with slippage of longitudinal reinforcement in reinforced concrete or with X-braced steel frames driven by high-shear loads. Baber and Noori (1986) introduced a slip-lock element behaving quite similarly to a hardening nonlinear spring, with the special characteristics that the “slip” zone stiffness is nearly zero, while the “lock” zone stiffness is infinite. The “slip” zone stiffness is initially zero and increases continuously as the system degrades with time. Thus, the pinching shape function $h(z)$ takes the form (Foliente 1995)

$$h(z) = 1 - \zeta_1 e^{-[z \operatorname{sgn}(\dot{x}) - q z_u]^2 / \zeta_2^2} \quad (9)$$

where sgn is the signum function and z_u is the ultimate value of z given by

$$z_u = \left(\frac{A}{v(\beta + \gamma)} \right)^{1/n} \quad (10)$$

The two functions $\zeta_1(\varepsilon)$ and $\zeta_2(\varepsilon)$ control the progress of pinching and are written as

$$\zeta_1(\varepsilon) = \zeta_s \left[1 - e^{(-p \varepsilon)} \right] \quad (11)$$

$$\zeta_2(\varepsilon) = (\psi + \delta_\psi \varepsilon)(\lambda + \zeta_1) \quad (12)$$

Six pinching parameters ζ_s , q , p , ψ , δ_ψ , and λ are therefore present. Altogether there are thirteen loop parameters of hysteresis: A , α , β , γ , n , δ_v , δ_η , ζ_s , q , p , ψ , δ_ψ , and λ . This generalized model of hysteresis possesses all the important features observed in real structures, which include strength degradation, stiffness degradations, and pinching of the successive hysteresis loops.

Compared with other parametric models, a differential model of hysteresis has many advantages (Foliente 1995; Song and Der Kiureghian 2006). The primary one is its ability to generate a large variety of realistic hysteresis loops. Another advantage is the coupling of the equation of motion (1) to either Eqs. 3 or 4 to form an overall differential system. This greatly facilitates any theoretical and numerical manipulations.

Nonetheless, it should be noted that the differential model is one-dimensional and cannot account for interactions between loadings in different directions. There are generalizations in which the differential model is augmented to a multi-degree linear system (Roberts and Spanos 1990). In such generalizations, however, it is also assumed that the system could be decoupled. Since no new physics is obtained, these generalizations would not be pursued herein. Finally, it must be emphasized that the extended Bouc–Wen model of hysteresis is an empirical model. As such, it is not derivable from the fundamental postulates of mechanics and the exact physical meanings of its thirteen parameters are not fully understood. The probable role played by each parameter is summarized in Table 1. Also contained in Table 1 are the sensitivity rankings (Ma et al. 2004) of the control parameters. As will be explained in the next section, in system identification, it is required to estimate only a subset of the 13 unspecified parameters.

System Identification

In analysis, the response of a system is sought if the system model and excitation are known. This is sometimes termed a forward problem. In this interpretation, the inverse problem of finding a system model given the excitation and response is called system identification. System identification in the time domain involves the determination of unspecified parameters of an assumed system model. This can always be formulated as an optimization problem. In the present context, suppose the differential model of hysteresis is adopted and a set of measured excitation–response data from cyclic performance tests of an inelastic structure is given. How can the loop parameters of hysteresis be estimated from the measured data? For each choice of the parameters, the response of the degrading structure subjected to the given excitation can be obtained by numerical simulation. The calculated response data can then be compared to the measured data to see if there are large errors. Obviously, the assumed loop parameters

Seismic Response Prediction of Degrading Structures, Table 1 Parameters of the generalized differential model of hysteresis

Parameter	Description	Local sensitivity ranking (highest = 1)	Global sensitivity ranking (highest = 1)
α	Ratio of linear to nonlinear response	1	2
A	Basic hysteresis shape control	Not varied	Not varied
β	Basic hysteresis shape control	5	4
γ	Basic hysteresis shape control	6	5
n	Sharpness of yield	8	7
δ_v	Strength degradation	12	9
δ_η	Stiffness degradation	4	8
ζ_s	Measure of total slip	2	1
q	Pinching initiation	9	6
p	Pinching slope	3	10
ψ	Pinching magnitude	7	3
δ_ψ	Pinching rate	11	12
λ	Pinching severity	10	11

provide a good fit if the errors are small. Thus, this amounts to estimating the 13 control parameters of the differential model of hysteresis when a load–displacement trace is given. The optimization problem can be stated as the determination of the parameter vector

$$\mathbf{p} = (A, \alpha, \beta, \gamma, n, \delta_v, \delta_\eta, \zeta_s, q, p, \psi, \delta_\psi, \lambda) \quad (13)$$

such that the objective function

$$g(\mathbf{p}) = \frac{1}{N} \sum_{j=1}^N [x(t_j) - \hat{x}(t_j|\mathbf{p})]^2 \quad (14)$$

is minimized. In the above expression, t_j is a sequence of time instants and $x(t_j)$ is the given system displacement at t_j , where $j = 1, 2, \dots, N$. On the other hand, $\hat{x}(t_j|\mathbf{p})$ is the system displacement at t_j calculated from Eqs. 1 and 4 when the parameter vector is equal to $\mathbf{p}$. The chosen objective function is simply the mean-square error in the displacement. Minimization of the objective function is subjected to the constraint that all parameters in $\mathbf{p}$ with the exception of γ are positive (Ma et al. 2004).

Early studies of parametric identification of hysteresis typically employed the non-degrading classical differential model containing only five parameters (Kyprianou et al. 2001; Ni

et al. 1998). In the few studies that involved degradation (Furukawa and Yagawa 1997; Sues et al. 1988; Zhang et al. 2002), either a restricted Bouc–Wen model containing less than thirteen parameters or a restricted identification algorithm was used. For example, Zhang et al. (2002) used gradient-based local-search algorithms to estimate some of the hysteretic control parameters for degrading structures. However, the generalized differential model of hysteresis is highly nonlinear and any gradient-based method tends to be trapped near local minima and therefore fails to converge. A robust and efficient identification algorithm is needed to estimate all thirteen unspecified parameters of the differential model of hysteresis (Ma et al. 2006).

Reduction of Parameters

In order to streamline the identification of the control parameters of differential hysteresis, the generalized Bouc–Wen model has been reexamined (Ma et al. 2004). Two significant issues have been uncovered. First, it was discovered that the unspecified parameters of the differential model are functionally dependent. One of the 13 control parameters can be eliminated through suitable transformations in the parameter space. The number of unspecified parameters can thus be reduced from 13 to 12 without any loss of

generality. Elimination of a parameter will appreciably accelerate the convergence of any identification algorithm. As explained by Ma et al. (2004), a convenient way to eliminate one parameter is to map the parameter A into 1. Henceforth, $A = 1$ will be assumed, and there remain twelve loop parameters in the differential model of hysteresis.

The second issue uncovered is the existence of insensitive parameters in the generalized Bouc–Wen differential model: the variations of three or four control parameters in the generalized model do not appreciably alter the computed hysteretic evolution of the system. Through local and global sensitivity analyses (Iman and Helton 1991; Ma et al. 2004), the twelve remaining parameters are ranked in order of decreasing sensitivity, as shown in Table 1. The method of global analysis employed is a probabilistic method recently expounded by Sobol (1993). It can account for the mutual interactions of the twelve parameters. On an overall basis, δ_v , δ_ψ , and λ are the least sensitive parameters. In the identification of hysteresis, these parameters are likely to slow down numerical convergence. One extreme measure to deal with this problem is to set the insensitive parameters to constants in the beginning; at any rate they need not be estimated with high precision. It is decided in this investigation that a two-stage procedure will be adopted to streamline the identification process. In the first stage, the three least sensitive parameters δ_v , δ_ψ , and λ are fixed, and a crude value of the nine-parameter vector

$$\mathbf{p}_1 = (\alpha, \beta, \gamma, n, \delta_\eta, \zeta_s, q, p, \psi) \quad (15)$$

is first estimated by minimization of the objective function in Eq. (14). This crude value of $\mathbf{p}_1$, together with the fixed values of δ_v , δ_ψ , and λ , is then used as seeds in a second-stage identification to estimate the optimal value of the twelve-parameter vector

$$\mathbf{p}_2 = (\alpha, \beta, \gamma, n, \delta_v, \delta_\eta, \zeta_s, q, p, \psi, \delta_\psi, \lambda) \quad (16)$$

In the identification of hysteresis, this two-stage procedure economizes on both computer core memory and computing time.

Nonlinear Optimization Algorithms

The goal of an optimization problem is to find a vector $\mathbf{p}^*$ in the search space S so that certain quality criterion is satisfied, namely, the error norm $g(\mathbf{p})$ in Eq. 14 is minimized. The vector $\mathbf{p}^*$ is a solution to the minimization problem if $g(\mathbf{p}^*)$ is a global minimum in S . For the constrained nonlinear optimization problem associated with the identification of differential hysteresis, the error surface defined by the objective function and constraints can exhibit many local minima or can even be multimodal. For this reason, different solution techniques will have dramatically different performance. The primary consideration in evaluating an optimization algorithm may be convergence speed or the minimum error achieved. Secondary consideration may be consistency, robustness, computational efficiency, or tracking capabilities.

Solution techniques are classified into local or population search. Basic local-search methods rely on iterative descent toward a minimum in which the direction of descent depends either on the gradient $\nabla g(\mathbf{p})$ or the Hessian matrix $\nabla^2 g(\mathbf{p})$ of the objective function. There are drawbacks of most gradient-based techniques, which include difficulties in calculating the gradient and frequent trapping of the iterates near a local minimum (Bertsekas 1999). In view of that, Zhang et al. (2002) used a non-gradient method based upon the Nelder and Mead simplex method to minimize the objective function $g(\mathbf{p})$ in Eq. 14. The simplex method explores the search space S either by reflecting, contracting, or expanding away from the worst vertex or shrinking toward the best vertex. An appropriate sequence of such movements converges to the nearest local minimum. This downhill simplex method requires only function evaluations and not derivatives. However, even this method does not have desirable convergence properties.

Population-based methods, also known as evolutionary computations, search the entire solution space S by maintaining a group of candidate vectors. Evolutionary techniques are inspired by natural evolution and adaptation with the essence of survival of the fittest. During the iterative process, new candidate vectors are

generated from existing ones by means of variation and selection such that the set of candidates would move toward increasingly favorable regions of the search space. Variation is achieved by first combining several candidate vectors to form a new one and then performing a random modification of the components of the resulting vector. Selection is introduced by comparing the fitness of the candidate vectors; the smaller the objective function $g(\mathbf{p})$, the fitter the vector $\mathbf{p}$. The fitter vectors will be selected to survive and become members of a new generation. Popular evolutionary techniques include genetic algorithms (Goldberg 1989), evolution strategies (Schwefel 1995), and differential evolution (Kyprianou et al. 2001; Lampinen and Storn 2004). Instead of performing sequential search as in the von Neumann architecture, evolutionary techniques employ massively parallel schemes with many computational elements connected by links of various weights. As a consequence, these techniques tend to be relatively robust because the risk of being trapped near a local minimum is significantly reduced. The trade-off is that evolutionary techniques are relatively slow compared with gradient methods. Genetic algorithms require conversion of floating-point values into bit strings and are less efficient for problems in which the parameters are real valued. For most floating-point problems, evolution strategies are more complicated and computationally involved than differential evolution. Differential evolution emerges as the best evolutionary method for use in the identification of hysteretic parameters of the generalized Bouc–Wen model.

Differential Evolution

Differential evolution is a relatively new and efficient approach for minimizing real-valued nonlinear and non-differentiable continuous-space functions (Price and Storn 1997). Let K be the dimension of the parameter vector $\mathbf{p}$ in Eq. 13. Suppose each generation in differential evolution consists of a population of P vectors. New vectors are generated in successive generations through certain mechanisms such that the vectors are getting closer and closer to the optimal value.

Basic mechanisms of differential evolution can be described as follows:

Initialization. In the beginning, the population can be initialized with random values chosen within boundaries specified by constraints if there is no prior knowledge about the system. Alternatively, a uniform probability distribution of the initial parameters may be assumed.

Mutation. Suppose all P vectors in generation G have been constructed. Denote these vectors by $\mathbf{v}_{i,G}$, where $i = 1, 2, \dots, P$ and every vector has dimension K . For each population member $\mathbf{v}_{i,G}$, a mutated vector $\mathbf{w}$ is generated by adding the weighted difference between two population members to a third member such that

$$\mathbf{w} = \mathbf{v}_{r_3,G} + F(\mathbf{v}_{r_1,G} - \mathbf{v}_{r_2,G}) \quad (17)$$

In the above expression, $0 < r_1, r_2, r_3 \leq P$ are three different integers chosen randomly, and $0 < F \leq 1$ is a preselected real-valued scaling factor. A common variation of mutation is to use the fittest vector $\mathbf{v}_{\text{best},G}$ of the current generation in place of $\mathbf{v}_{r_3,G}$ in Eq. 17.

Crossover. In order to increase the diversity of the population, the operation of crossover between $\mathbf{v}_{i,G}$ and $\mathbf{w}$ is performed. First, independent uniform random numbers $z_1, z_2, \dots, z_K$ are generated. With a preselected crossover constant $0 \leq CR \leq 1$, a trial vector $\mathbf{u} = [u_1, u_2, \dots, u_K]^T$ is constructed by means of

$$u_j = \begin{cases} w_j & \text{if } z_j < CR \\ (\mathbf{v}_{i,G})_j & \text{otherwise} \end{cases} \quad (18)$$

The constant CR determines whether each component of the vector $\mathbf{u}$ will originate from the mutated vector $\mathbf{w}$ or from the current vector $\mathbf{v}_{i,G}$. In essence, CR controls the probability that a crossover would occur for each component of the trial vector $\mathbf{u}$.

Selection. The selection process is performed by a one-to-one competition in which the fitness of a vector is determined by its objective value, which is calculated by Eq. 14 with a fourth-order Runge–Kutta method for numerical integration. The trial vector $\mathbf{u}$ is then compared to the

Seismic Response Prediction of Degrading Structures, Fig. 2 Basic mechanisms of differential evolution

vector $v_{i,G}$. If the vector u yields a smaller objective value, it replaces $v_{i,G}$ as $v_{i,G+1}$ in generation $G+1$. Otherwise, the original vector $v_{i,G}$ will be kept. The process of mutation, crossover, and selection of the differential evolution algorithm is summarized in Fig. 2. The process is repeated P times to construct all vectors of generation $G+1$. As evolution progresses, new generations of vector members become fitter and fitter as the objective values decrease.

In the differential evolution algorithm, three control parameters P , F , and CR must be preselected. Lampinen and Storn (2004) indicated that convergence of differential evolution is not particularly dependent upon the choice of these control parameters. It suffices to choose F and CR as multiples of 0.1 and P as a multiple of 10. Finally, a convergence criterion is needed to determine if the evolution process has converged. A common procedure is to set a desired objective value or to establish a threshold based on the relative fitness between the best and the worst vectors in each generation. Another method is to require a minimum percentage of improvement in fitness in order to continue the iteration process. One may also limit the number of generations or the computing time or both. Each convergence criterion has its advantages and drawbacks. Thus, a combination of convergence criteria is often used.

Based upon the exposition in this section, a robust algorithm using the latest theory of differential evolution is constructed for the identification of differential hysteresis. As explained before, a two-stage procedure is adopted whereby a crude value of the vector p_1 in Eq. 15 is first obtained before the optimal value of p_2 in Eq. 16 is computed. In simulations reported in this entry, the population size P is set to 100, while both the scaling factor F and the crossover constant CR are set to 0.5. The computing time is dependent on the amount of input data used for identification. The runtime can be reduced appreciably if some of the insensitive parameters are fixed and parallel computing is utilized.

Prediction of Performance

With a robust and relatively efficient algorithm devised in section “[System Identification](#),” a differential model of hysteresis of any degrading system may be identified from a given load–displacement trace. Suppose a hysteretic model is generated with a given load–displacement trace. It will be shown that, under fairly broad conditions, the model predicts the response of the same structure when driven by other cyclic loads. This can be carried out experimentally by building a number of identically configured structural joints

and subjecting them to different cyclic loads. One set of load–displacement trace is chosen to generate a hysteretic model of the joint by system identification. Subsequently, this identified model is used to compute the displacements of the joint under other cyclic loads. The computed displacements will be compared with experimental measurements. A reasonable match will validate the identified model and will demonstrate its prediction capability. In order to reduce the front-end costs of this investigation, only wood joints are used in the experiments. It must be emphasized that steel and concrete structures may be used as easily. Although a limited set of experimental data will be presented in this entry, many different structural joints have been built and tested to support any observations made herein.

Test Setup

Cyclic tests of degrading structures are performed in the Forest Products Laboratory located at the Richmond Field Station of the University of California, Berkeley. Twenty identical specimens of a simple *T*-connection consisting of two wood members joined by plywood gusset plates, as shown in Fig. 3, are constructed. The two wood members are made out of laminated veneer lumber (LVL), which is a highly predictable engineered wood product with relatively small material variability. Each LVL member is a uniform beam with a square cross section of 3.5×3.5 in. and an elastic modulus of 2.0×10^6 psi. The LVL lumber is sawn to consistent sizes and is virtually free from warping and splitting. The two LVL members are connected on both sides by plywood gusset plates of 0.5 in. thickness. Six 2-in. metal screws are arranged in three rows to fasten the plates to the vertical beam. The two plates are also connected securely to the horizontal beam with four metal screws and two retrofit bolts. Cyclic loads are applied parallel to the lower beam at a height 36 in. above the lower beam. The arrangement is such that the *T*-connection will fail through detachment of vertical LVL member from the gusset plates.

Seismic Response Prediction of Degrading Structures, Fig. 3 Reaction frame test system with a specimen

Common seismic testing protocols are employed to drive the *T*-connections. It is claimed that such protocols would simulate damage accumulation and degradation of the structural joint under real-life loads. Three of the cyclic excitations used in the experiments are shown in Figs. 4, 5, and 6. Excitation A is proposed by the Consortium of Universities for Research in Earthquake Engineering (CUREE), developed exclusively for wood testing (Krawinkler et al. 2001). The CUREE protocol is designed to model ordinary ground motion typical of most far-field locations. It is characterized by a pattern of a primary cycle followed by a number of trailing cycles that are 75 % of the previous primary cycle. Each primary cycle, which has higher amplitude, initiates a new level of damage to the structure. Damage then accumulates and changes the structural response in the trailing cycles. In addition, the number of reversed cycles is limited in order to induce failure modes resembling those in actual structures.

Seismic Response Prediction of Degrading Structures, Fig. 5 Excitation of Forintek Canada Corporation

Seismic Response Prediction of Degrading Structures, Fig. 6 Excitation of Forest Products Laboratory

Excitation *B* is devised by Forintek Canada Corporation (FCC), a national wood products research institute in Canada. Compared with excitation *A*, equal-amplitude primary and trailing cycles are used in this excitation. The FCC protocol consists of a sequence of cyclic

groups, each composed of three identical cycles. The amplitude of each group is taken as a percentage of the nominal yield slip and is increased stepwise, with inter-spaced decreasing cycles until the specimen fails. Excitation *C* was developed at the Forest Products Laboratory for the

Seismic Response Prediction of Degrading Structures,

Fig. 7 Hysteresis loops generated by excitation *C* in 500 s

experiments reported herein. This protocol features trailing cycles that are decreasing in amplitude, which are different from the equal-amplitude trailing cycles in the CUREE and FCC excitations. In addition, excitation *C* does not have the series of low-amplitude cycles featured in the starting interval of excitation *A*.

Model Identification and Validation

Each specimen of the identically configured *T*-connections is driven by a cyclic excitation and 1,000 s of load–displacement data are recorded. Using any of these load–displacement traces, a model of hysteretic evolution can be identified. Two issues will now be examined. (1) Can a hysteretic model identified with a given cyclic load predict the future structural response if the *same* cyclic load continues beyond the duration used for identification? (2) Can a hysteretic model identified with a given cyclic load predict the structural response due to a *different* cyclic load?

In Fig. 7, the load–displacement trace associated with excitation *C* for the first 500 s is shown. As reflected in the hysteresis trace, the gusset joint is degrading in both strength and stiffness. There is also some pinching of the hysteretic loops, which is probably caused by slipping of the connecting screws. The load–displacement trace of Fig. 7 is used as input to the identification

algorithm devised in the last section. Recall that $A = 1$, and there remain twelve hysteretic parameters to be estimated of the gusset-plate connection. Once these twelve parameters are identified, a hysteretic model of the *T*-connection is obtained. This hysteretic model can now be used to compute the displacement history of the gusset joint associated with excitation *C*. As illustrated in Fig. 8, the computed displacement history closely matches the experimental measurements. This validates the identified hysteretic model over the first 500 s.

A different hysteretic model of the *T*-connection is generated when the duration of input data changes. In Fig. 9, the load–displacement trace associated with excitation *C* for $0 < t < 1,000$ s is shown. Compared with Fig. 7, pinching is more prominent after the first 500 s. Thus, the twelve control parameters estimated with input data of Fig. 9 are different from those associated with Fig. 7. The new hysteretic model must be validated again for a duration of 1,000 s because the dominant characteristics of degradation are different between the two intervals $0 < t < 500$ s and $0 < t < 1,000$ s. A hysteretic model identified with input data over $0 < t < 500$ s will not produce a displacement history closely matching the experimental data over $500 < t < 1,000$ s. In short, system identification cannot produce

Seismic Response Prediction of Degrading Structures, Fig. 8 Comparison of computed and measured displacements under excitation *C*

Seismic Response Prediction of Degrading Structures,

Fig. 9 Hysteresis loops generated by excitation *C* in 1,000 s

features and trends not already contained in the input data. If the duration of input used for identification already contains all features of hysteretic evolution, then a hysteretic model identified with a given excitation can accurately predict the future response when the *same* excitation continues beyond the duration used for identification. This basically answers the first question brought up at the beginning of this section.

In identifying a hysteretic model of the *T*-connection, the experimental load–displacement trace associated with excitation *C* has been used

directly as input for identification. It can be argued that such input data are corrupted by Gaussian noise, and a more accurate model can be identified if noise is suppressed with a filter. To this end, the input was first taken through a median filter and then a least-squares low-pass filter. Such a filtering process is known to be effective in smoothing out random fluctuations caused by Gaussian noise (Papoulis and Pillai 2002; Zhang et al. 2002). However, it has been found that a better match than what is shown in Fig. 8 is not achieved with the noise-filtered data. It appears that differential evolution is not sensitive to a moderate level of

Seismic Response Prediction of Degrading Structures, Fig. 10 Predicted and measured displacements under excitation A in 1,000 s

Seismic Response Prediction of Degrading Structures, Fig. 11 Predicted and measured displacements under excitation B in 1,000 s

Gaussian noise. Subsequently, noise-filtering is not used on any of the load–displacement traces.

Can a hysteretic model obtained by identification using a given excitation predict the structural response due to a *different* cyclic load? This is the second question brought up earlier. Using 1,000 s of the load–displacement trace associated with excitation C, a hysteretic model of the T-connection has been identified. Keep in mind that other cyclic loads do not play any part in the identification of hysteresis. The identified model is then used to compute the displacement of the gusset joint under excitation A of Fig. 4. However, load–displacement data associated with excitation A have already been collected experimentally using another specimen of the identically configured gusset joints. Thus, the

computed (or predicted) displacement can be compared with the measured displacement. As shown in Fig. 10, there is reasonably good match. A similar observation can be made with other cyclic loads. As illustrated in Fig. 11, there is also reasonably good match between the computed (or predicted) and experimental data when excitation B of Fig. 5 is used. This demonstrates that a hysteretic model identified with a given excitation may be used for response prediction under different excitations. However, the accuracy of prediction tends to diminish as time increases.

Requirements for Accurate Prediction

As demonstrated in previous sections, a hysteretic model obtained by identification can be used

Seismic Response Prediction of Degrading Structures,

Fig. 12 Failure configuration of *T*-connection under excitation *C* over 1,000 s

to predict future performance of a system. Large errors, however, can arise in many cases. For example, the prediction of response associated with excitation *A* is no longer satisfactory after 900 s, as shown in Fig. 10. Perhaps this is not surprising. As time progresses, damage accumulates and the *T*-connection begins to fail. There is, however, a divergence in the failure configuration due to different excitations.

As shown in Fig. 12, a typical failure configuration under excitation *C* over 1,000 s is that the top two screws in the vertical member are appreciably loosened due to wood crushing. Disassembly of the gusset joint reveals that both screws are broken into two pieces under excitation *C*. If 1,000 s of the load–displacement trace associated with excitation *C* is used for identification, a hysteretic model is generated that anticipates the breaking of the top two screws. Under excitation *A*, however, it has been observed that all four screws in the top two rows are broken over 1,000 s, as shown in Fig. 13. If a model identified with excitation *C* is used for response prediction when the structure is driven by excitation *A*, it fails to predict that all four screws in the top two rows would be broken over 1,000 s. This explains the discrepancy between the predicted and measured displacements under excitation

Seismic Response Prediction of Degrading Structures, Fig. 13 Failure configuration of *T*-connection under excitation *A* over 1,000 s

A in Fig. 10. If the failure mechanism can be controlled, the accuracy in response prediction will be increased.

The observations made in experimenting with the elementary *T*-connection can be extended to complex assemblies or structures. A complex structure consists of many different elementary connections. Since each elementary connection may have several failure configurations, the totality of failure configurations is very large for a complex structure. If structural degradation can be controlled so as to result in a failure configuration identical to what is contained in the input data used for identification, then nonlinear degrading response of a complex structure can be predicted. Otherwise, prediction is only reliable up to a point at which the input data and the existing complex structure progress into different failure configurations. A study of the influence of failure configurations on the reliability of response prediction will be worthwhile in a subsequent course of investigation.

Summary

A basic objective of this entry is to advance the methodology for predicting the performance of nonlinear deteriorating structures. Using the generalized Bouc–Wen differential model, it is shown how system identification can be utilized to predict the response of a degrading structure well beyond its linear range. Important observations reported in the paper are summarized in the following statements.

1. A robust identification algorithm based upon the generalized Bouc–Wen model and the theory of differential evolution can be used to generate practical models of hysteresis of degrading structures. Differential evolution is not sensitive to a moderate level of input noise.
2. If the duration of input used for identification already contains all features of hysteretic evolution, then a hysteretic model identified with a given cyclic load can accurately predict the future structural response when the same cyclic load continues beyond the duration used for identification.
3. A hysteretic model identified with a given cyclic load may be used to predict the nonlinear response under different cyclic loads. As damage accumulates, the precision of predicted response decreases, and the reliability of prediction ultimately depends on the degree of similarity between failure configurations under different cyclic loads.

In the absence of a fundamental theory of degradation, the response prediction of degrading structures is indeed a challenging task. System identification of hysteretic evolution provides a brute-force procedure for prediction that has the potential of allowing a closer representation of reality. The research reported herein addresses various aspects of an identification methodology for predicting the performance of real-life deteriorating structures well beyond their linear ranges. Among other things, it is hoped that this entry would point to directions along which further research efforts should be made. This entry could also contribute to the development of a general formulation of the mechanisms of degradation in the long term.

Domino effects; Short-term hazard and risk assessment; Time-dependent risk; Triggering effects

Introduction

Risk is conveniently assessed as a function of the probability that a certain event will occur and of the extent of the damage caused to humans, environment, and objects. Conceptually, it is the result of the operation

$$\text{Risk} = \text{Hazard} \times \text{Damage} = \text{Hazard} \times \text{Vulnerability} \times \text{Value at Risk} \quad (1)$$

where the *Hazard* can be understood as the probability that a given adverse event of a given intensity (hereinafter referred to as *intensity measure*, IM) will occur in a certain area within a defined time interval; the *Vulnerability*, a concept interpreted and applied in various ways, here is considered in its physical dimension as the probable damage to an element at risk given a level of intensity (IM) of the hazard; and the *Value at Risk* term is considered as a measure of the total potential loss due to an adverse event in a given area.

Note that both *Hazard* and *Vulnerability* are generally defined in probabilistic terms, while *Value at Risk* has some defined units of measure (monetary cost, number of human lives, etc.).

Seismic risk assessment methods have shown an important development over the last 40 years reaching an outstanding level of acceptance by the scientific community as a valid framework for sound risk mitigation and decision-making. In general the seismic risk assessment uses seismic hazard information combined with fragilities of structures and facilities in order to estimate the probabilities of damages and to measure expectancies of losses using a predefined metric of loss.

Different past disasters have highlighted the fact that natural or man-made events can trigger other events, leading to a significant increase of fatalities and damages. As a consequence, there is a growing demand from risk managers to implement multi-type hazard and risk assessments as well as assessing cascading effects. Consequently, an increasing number of scientists studying natural hazards and risk assessment are turning their interest towards the multi-hazard risk and multi-risk assessment practice. The transition from the single- to the multi-risk assessment represents a process in which both the complexity and the data requirements are significantly increased. This transition implies a shift from the “hazard-centered” perspective that characterizes the single-risk assessment to a “territorial-centered” one.

The cascading events are one of the fundamental concepts of the multi-risk assessment. It is worth noting that a different terminology is used in the practice of risk evaluation when addressing the problem of chains of events. In particular, the term “domino effect” is generally used in the field of industrial accidents, whereas the term “cascading effects” is mainly used in ecology and in natural hazards in the context of the multi-risk assessment. The objective of this entry is to discuss the role of cascading effects triggered by earthquakes and its importance for a holistic view of the seismic risk assessment process.

Multi-risk as a Framework for the Assessment of Cascading Effects

The transition from single- to multi-risk assessment represents a process in which both the complexity and the data requirements are significantly increased (Fig. 1a). This transition implies a shift from a “hazard-centered” perspective that characterizes the single-risk assessment, to a “territorial-centered” one. In fact, from a multi-risk perspective, the first element to be defined is the target area of interest, which is in general terms the piece of territory composed of elements at risk that are vulnerable in different ways to various sources of hazard.

The evolution from the single-risk to the multi-risk analysis consists of three different and complementary elements: the single-risk assessment (SR), the multi-hazard risk assessment (MHR), and the multi-risk assessment (MR).

Figure 1 represents the transition from the SR to the MR assessment (Fig. 1a). The hazard-centered perspective of the SR is represented in Fig. 1b; in this case, the first element of the analysis is generally the hazard source followed by the definition of the impact area and the assessment of the potential effects. The change towards a territorial perspective is represented in Fig. 1c. In the MHR, different independent hazard sources affecting a given common area of interest are considered; in this case, the first element of the analysis is the definition of the piece of territory which is the target area for the analysis; the target area includes the elements at risk exposed to adverse events. Note that this change in perspective is common to both the MHR and the MR assessments. Once the target area has been identified, the next element of the analysis is the identification of the potential hazard sources that may cause harm to the set of exposed elements in the target area.

Figure 1d illustrates how each element in this transition is a subset in the higher levels of the sequence. In fact, a set of SR analyses compose an MHR analysis, and when the MHR assessment is complemented with the analysis of interactions

Seismic Risk Assessment, Cascading Effects, Fig. 1 Representation of the transition from the single- to the multi-risk assessment

among events, then the MR level is reached. This sequence is of course valid if the SR and MHR analyses are done coherently in a multi-risk framework, following some basic (and often non-simple) elements of harmonization.

The multi-risk assessment (MR) is then a generalization of the MHR assessment in the sense that it integrates also the possible interactions or cascading effects (Fig. 1c, d); therefore, the main objective of the MR assessment level is to assess the effects of possible interactions or cascading effects among the different hazardous events. Considering long- and short-term assessments, Marzocchi et al. (2012) identify the following main steps of the MR assessment procedure:

1. Definition of the space-time window for the risk assessment and the metric for evaluating the risks
2. Identification of the risks impending on the selected area
3. Identification of selected hazard scenarios covering all possible intensities and relevant hazard interactions
4. Probabilistic assessment of each scenario
5. Vulnerability and exposure assessment for each scenario, taking into account the vulnerability of combined hazards
6. Loss estimation and multi-risk assessment

In this framework, a set of scenarios considering adverse events from different sources are identified along with the potential interactions. Each chain of adverse events is defined in a series/parallel sequence of happenings and is generally represented in an “event tree.” Each branch of the event tree is quantified by a probabilistic analysis considering the sequence of the events and the vulnerability and the exposed values of the specified targets. This concept is illustrated in Fig. 2, where the possible kinds of interactions are identified using discontinuous red lines. For example, a sequence defined for independent hazards interacting at the vulnerability (or damage) level is represented by the red discontinuous line in the sequence at the left side of Fig. 2. Likewise, an example of interaction at the hazard level is presented with source 3 triggering source 2 (see the path defined with the red discontinuous line at the right in Fig. 2). Note that

Seismic Risk Assessment, Cascading Effects, Fig. 2 Multi-risk framework considering possible interactions at the hazard and the vulnerability levels (Reproduced from Marzocchi et al. 2012, with permission from Springer®)

in this case, the interaction at the vulnerability level may or may not be present. Details about the kinds of interactions are more deeply presented in the following sections of this entry.

Within this context of interactions and triggering mechanisms, earthquake-triggered events have drawn much attention in the last decades because of the severe damages that the triggered

events may cause. Sometimes, the losses caused by the secondary events may exceed the losses caused by the initial, triggering earthquake itself. For example, in a number of earthquake-triggered landslides, the losses caused by the triggered mass movements have been comparable (if not higher) to the losses caused by the direct impact of ground shaking. An outstanding case is the Huascarán rock-debris avalanche triggered by the M7.7 Peru earthquake in 1970 (e.g., Plafker et al. 1971), in which the impact of the avalanche counts for more than 50 % of the total casualties.

The kind of events that can be triggered and the possible interactions that can be analyzed vary in a wide spectrum of events including natural (as other earthquakes, landslides, tsunamis, volcanic unrest and eruptions, etc.) and nonnatural (as Natech) events. A non-exhaustive description of known examples is presented in the section [“Examples of Cascading Effects Caused by Earthquakes.”](#)

Cascading Effects: An Overview

From the risk assessment point of view, the cascades of events occurring after an earthquake may represent an important source of loss amplifications. In this context, we consider as “*loss amplification*” all the losses not caused directly by the earthquake (as the triggering event) but caused by other secondary events occurring as a consequence of the initiating triggering event. Therefore, the loss amplification can be a factor resulting from comparing the total losses caused by the chain of events triggered by an earthquake with the direct losses caused by the initial earthquake itself.

The cascading effects result as a consequence of interactions generated by cause/effect relationships among different phenomena. The nature of these interactions may be described by a wide set of phenomenological relationships, and it makes difficult to set a generalized procedure for the quantification of cascading effects. For this reason and to simplify the setting of the problem for quantitative purposes, a generic taxonomy of the

possible kinds of interactions can be defined. Following the framework presented in Marzocchi et al. (2012), Garcia-Aristizabal et al. (2013), and Garcia-Aristizabal et al. (forthcoming-2015), we can consider the following two major sets of interactions: (1) interactions at the hazard level and (2) interactions at the vulnerability level. This generic taxonomy of possible interactions is qualitatively described in the following paragraphs, and a more quantitative definition is presented in the last section of this entry.

Interactions at the Hazard Level

In this case the interaction problem is understood as the assessment of possible chains of adverse events in which the occurrence of a given initial “triggering” event entails a modification of the probability of occurrence of a secondary event. Even if this typology of problem can be assessed on a long-term basis, its utility can be highlighted in short-term problems. It can be seen that the typology of interactions that can be grouped under this name are in fact phenomena in which the physical process of interest is a pure triggering mechanism in which a first occurring event produces a perturbation that, when acting over a given system, may bring it to unstable conditions forcing it to find a new equilibrium. Reaching this new equilibrium may imply the occurrence of an event that in this case may be said as *triggered* by the initial triggering one.

The link between the intensity of the triggering event (e.g., the ground shaking caused by an earthquake) and the intensity of the triggered event (e.g., a volume of mass moving in a slope) is governed by complex physical mechanisms that are intrinsically related to the specific triggering and triggered events. This fact and the ubiquitous random effects that may affect these processes make of probabilistic approaches the most promising way for the quantitative characterization of such interactions. Therefore, assessing interactions at the hazard level in probabilistic terms implies to quantify the conditional probabilities of occurrence of the triggered event, given the occurrence of the triggering event (with given intensity).

Interactions at the Vulnerability Level

In this case the problem fundamentally intends to assess the effects that the simultaneous occurrence of two or more events (not necessarily linked) may have on the response of a given typology of exposed elements. In this case, the process of interest is the additive effect of different events acting on the same elements. More specifically, this kind of interaction is referred to the case in which the occurrence of one event (the first one occurring in time) may alter the response of the exposed elements against another event (that may be of the same kind as the former but also a different kind of hazard). In this case, it is assumed that two or more events act on a system (e.g., a structure) and that the additive or cumulated effect produces a change in the response of the system with respect to the conditions before the occurrence of the former event. In practice, it implies that two or more hazardous events act simultaneously or in a short-time window (in general short enough that the system cannot be repaired) on the same structure.

The cases that can be grouped under this kind of interaction are of different nature; in general, the physical processes of interest are those related with the response of the system (in this case, an exposed element) to the loads caused by different events taking in account their additive or cumulated effects. Note that the different events may be of the same nature (i.e., same kind of hazards, as, e.g., two earthquakes shaking the same structures in a short-time window) or coming from different kinds of phenomena (e.g., the shaking caused by an earthquake as the first event, followed by loads caused by river flooding or strong wind). Note that the different events causing additive loads can be themselves the result of a common triggering event or may be independent events, and this relationship is important for the quantitative analyses.

As in the previous case, the quantitative assessment of this kind of interactions relies on probabilistic analyses. It may be understood as a multidimensional development of fragility functions for the different typologies of exposed elements. In general, it involves the determination of

the conditional probabilities of having certain damage state given the simultaneous or cumulative solicitation caused by different combinations of intensities of the different events considered. Note that this information can be represented in different ways, according with the nature of the acting events. For instance, if the acting events are not causing cumulated damages in the same elements (e.g., seismic loads from one side and the loading caused by snow accumulation or flooding water on the other), then the conditional probabilities define a multidimensional fragility surface. Conversely, if the different acting events produce cumulated damages in the same elements (i.e., when the first event pre-damages a given element, as, e.g., two earthquakes acting one after the other in a short time interval), the conditional probabilities are generally referred as *time-dependent* or *damage-dependent* fragilities (or vulnerabilities).

Examples of Cascading Effects Caused by Earthquakes

Many examples of cascading effects caused by earthquakes can be cited as, for example, the well-known cases of tsunamis triggered by earthquakes or earthquake-triggered landslides. As described in the previous section, there may be different typologies of interactions, and the physical processes involved in these interactions are extremely case dependent. In this section, we describe some outstanding cases of interactions (mainly at the hazard level) that highlight the potential loss amplifications that these triggering effects may produce.

Earthquake-Earthquake Triggering

Earthquake mainshocks cause aftershocks to occur, which in turn activate their own subsequent aftershock sequences, resulting in a cascade of triggering that may increase the damage caused to the exposed elements with respect to the effects directly produced by the mainshock alone. For this reason, contrary to the normal practice in seismic hazard and risk assessment, the cascade of seismic events triggered during a

seismic sequence must be of interest, at least in the short term.

A cascade of earthquakes triggering earthquakes causes the seismicity to develop in complex patterns (see, e.g., Marsan and Lengliné 2008). Different physical mechanisms have been proposed to study mainly the direct triggering problem; these include static stress changes (i.e., the difference in the stress field just before an earthquake to shortly after the seismic waves have decayed, see, e.g., Hill et al. 2002; Manga and Brodsky 2006), quasi-static stress changes (e.g., associated with slow viscous relaxation of the lower crust and upper mantle beneath the epicenter of a large earthquake, see, e.g., Hill et al. 2002), dynamic stress changes (i.e., induced by the seismic waves from a large earthquake, see, e.g., Hill et al. 2002; Manga and Brodsky 2006), and fluid flow (e.g., migrating pore fluids and pore pressure changes as a mechanism controlling the timing of aftershocks, see, e.g., Harris 1998 and references therein). The distinction between static and dynamic stress transfer mechanisms breaks down at distances less than a fault length from a given earthquake. That region, the *near field*, is generally the spatial domain of aftershock occurrences (Hill et al. 2002).

The evident complexity of the triggering problem explains the objective difficulty to efficiently discriminate between direct and indirect triggering in the observed data, limiting the possibility of implementing pure deterministic approaches for the analysis of the events in a sequence. Therefore, the main efforts, as found in literature, attempt to identify and separate earthquakes between mainshocks and aftershocks, with the most sophisticated methods employing stochastic approaches. Our discussion in this section is restricted to the description of stochastic modeling of aftershock sequences.

The statistical properties of the aftershock sequences have long been of interest to study the earthquake generation processes. It has resulted in the development of a number of point process models (a type of random process for which any realization consists of a set of isolated points in time or space) to describe the standard activity of earthquake sequences.

Considering in particular the *trigger models* (Vere-Jones and Davies 1966), it is assumed that the conditional probability of a shock occurring at a time t after a given triggering mainshock is proportional to a *decay function* $\lambda(t)$. In general, it considers that the triggering events occur by following a Poisson process with a constant rate, while the number of triggered events (i.e., the group of shocks initiated by a single triggering event) decays by following a prescribed function. Regarding the nature of $\lambda(t)$, Vere-Jones and Davies (1966) considered in detail two functions:

- An exponential decay, $\lambda(t) = pe^{-pt}$, ($p > 0$)
- An inverse power-law decay, $\lambda(t) = pc^p / (c + t)^{p+1}$, ($c > 0$)

(where the model parameters arise from the Omori formula). Vere-Jones and Davies (1966) suggested that the inverse power-law type of decay function gives a better fit than the negative exponential. Considering a restricted form of the trigger model, Ogata (1988) proposed the epidemic-type aftershock sequences (ETAS) model. ETAS is a stochastic point process in which each earthquake has some magnitude-dependent ability to trigger its own Omori law-type aftershocks. The total occurrence rate can be described, in time, as the superposition of a background uncorrelated seismicity μ_0 and the events triggered by another earthquake:

$$\lambda(t) = \mu_0 + \sum_{i:t_i < t} \lambda_i(t) \quad (2)$$

where $\lambda_i(t)$ is the rate of aftershocks induced by an event occurred at time t_i with magnitude M_i , defined as (Ogata 1988):

$$\lambda_i(t) = \frac{k}{(c + t - t_i)^p} e^{\alpha(M_i - M_c)} \quad (3)$$

for $t > t_i$. The parameter k measures the productivity of the aftershock activity; α defines the relation between triggering capability and magnitude M_i of a triggering event; c measures the incompleteness of the catalog in the earliest part of each cluster; p controls the temporal decay of

Seismic Risk Assessment, Cascading Effects, Fig. 3 Percentage of landslide events in Italy classified by the triggering mechanism (Source of the data: CNR-GNDCI – database of areas affected by landslides and floods in Italy)

triggered events; and M_c is the completeness magnitude of the data catalog. A space-time generalization of ETAS was later introduced by Ogata (1998). The ETAS model is widely used in different ways, as, for example, to describe short-term seismicity, in the forecasting of after-shock sequences (useful in short-term hazard studies) and also as a declustering method to separate the background seismicity from the triggered one.

From the perspective of considering cascading effects in the seismic risk assessment, the stochastic description of the seismic sequences (in particular by the ETAS model) has important consequences in probabilistic seismic hazard assessments, since it permits to take into account a more realistic behavior of the seismicity to calculate aftershock hazard curves, which is of fundamental importance for short-term hazard assessments.

It is worth noting here that considering the sequences of earthquakes in a chain of triggering effects can be regarded as an interaction at the hazard level (according to the taxonomy provided in this entry). Nevertheless, it may require also taking into account the cumulative effect of the different earthquakes on the exposed elements (e.g., the physical structures), which requires to consider also a possible interaction at the

vulnerability level by using damage-dependent fragilities.

Earthquakes as Triggering Mechanism of Landslides

Strong earthquakes may cause widespread landslides and other ground failure phenomena as, for example, liquefaction. A comprehensive historical review of outstanding past examples of earthquake-triggered landslides can be found in Keefer (2002) and references therein. In many cases the loss of lives and properties caused by the landslides exceed the losses caused by the earthquake itself (see, e.g., Chen et al. 2012). The occurrence of landslides can be associated with different triggering mechanisms as intense precipitation, erosion, ground shaking caused by earthquakes, groundwater variations, nonnatural effects of anthropic activity, etc. For example, let us consider the database from the “National Group for Prevention of Hydrological Hazards” of areas affected by landslides in Italy (CNR-GNDCI, <http://avi.gndci.cnr.it>); the most frequent kind of events triggering landslides in Italy are (see Fig. 3): the precipitation and infiltration (73.5 %), erosion (11.9 %), anthropic activity (5.1 %), earthquakes (2.6 %), and groundwater variation (1.4 %).

Taking as reference the available landslide catalog in Italy, about a 3 % of the total landslide occurrences in this area can be associated with earthquake-triggering mechanisms (Fig. 3). It is worth noting that this example is representative for the Italian area, and therefore the proportion of events for the different triggering phenomena may considerably change from one region to the other in function of different factors as, for example, the amount of precipitation, topography and land use, size and location of earthquakes, etc.

From the cascading effects assessment perspective, the occurrence of earthquakes in landslide-prone areas may increase the likelihood of landslide occurrence due to different physical mechanisms, as, for example, the inertial forces during the ground shaking itself or the rapid increase in pore water pressure induced by the cyclic stresses and subsequent reduction of the soil shear strength. Furthermore, earthquakes may reduce the soil strength for longer periods, causing the affected area to be more susceptible to post-earthquake rainfall-triggered landslides until the soil has regained its original strength.

Several models have been proposed for assessing the stability of slopes during earthquakes; an interesting overview of methods is provided in Jibson (2011). These methods are conveniently grouped into (1) pseudo-static analyses, (2) stress-deformation analyses, and (3) permanent displacement analyses. One of the most popular models in the latter group is that proposed by Newmark (1965), where the landslide is modeled as a rigid block sliding on an inclined surface. Movement of the block occurs when the sum of the static and dynamic driving forces exceed the shear resistance of the block. Permanent deformation occurs when the induced accelerations exceed some critical acceleration. The sliding block model assumes (1) a rigid-plastic behavior of the boundary between the surface and the sliding block, (2) the existence of a well-defined slip surface, (3) negligible loss in shear resistance during shaking, and (4) permanent displacement occurs only if dynamic stresses exceed shear resistance. A displacement can take place then during a cyclic load whenever the shear stress exceeds the base resistance, and

the block displacement ends when the block-base relative velocity equals zero. Displacement steps are summed over the entire duration of the acceleration-time history to obtain the total displacement. The method has undergone several modifications and improvements, and several relations between seismic ground-motion parameters and computed landslide displacements have been proposed. A particularly interesting application for quantitative hazard assessment of earthquake-triggered landslides is presented in Miles and Ho (1999), in which hazard analyses are performed combining Newmark's approach and Boore's stochastic ground-motion simulations. Likewise, stochastic methods for probabilistic earthquake-triggered landslide hazard assessment have been also proposed. For example, Jibson et al. (2000) performed a comparative analysis of the displacements modeled using the Newmark's permanent-deformation analysis and the landslide observations after the 1994 Northridge, California earthquake and used this information to construct a probability curve relating predicted displacement to probability of failure. Likewise, Refice and Capolongo (2002) presented a procedure that takes into account uncertainties and the spatial variability of geological, geotechnical, geomorphological, and seismological parameters in the Newmark slope stability model and applied it for probabilistic earthquake-triggered landslide hazard assessment.

Earthquakes Triggering Volcanic Eruptions

Deformation of the surrounding rocks is required for the magma movement before volcanic eruptions; therefore, small to moderate local earthquakes (usually called *volcano-tectonic* seismicity) normally precede and accompany eruptive activity. However, volcanic unrest episodes and volcanic eruptions have been observed within days after the occurrence of big earthquakes occurring outside the volcanic area. Evidences of tectonic earthquakes preceding volcanic activity can be found in different tectonic setting and on different time and distance scales (see, e.g., Eggert and Walter 2009; Gasparini 2013). Well-known cases of this

possible triggering effect may include, among many others, the 1990 M7.8 Luzon earthquake and the reawakening of Mount Pinatubo in 1991 (e.g., Bautista et al. 1996); the 1960 M9.5 Chile earthquake, which was followed about 38 h later by an eruption in the Puyehue-Cordón Caulle volcano (e.g., Barrientos 1994); Mount Vesuvius having the largest eruptions shortly after earthquakes in the Apennines (Nostro et al. 1998); and eruptions of different volcanoes in Kamchatka (some of them not considered active) following earthquakes in different periods (e.g., Karymsky and Dzenzur volcanoes erupting after an M8.5 earthquake in 1923, the Karpinsky volcano and the Tao-Rusyr Caldera erupting few days after an M9.0 earthquake, and the Karymsky and Akademia Nauk volcanoes erupting few days after a M7.1 earthquake, Walter 2007 and references therein).

Approximately 0.4 % of explosive volcanic eruptions occur within a few days of large, distant earthquakes, which is a value much greater than expected by chance (Manga and Brodsky 2006; Linde and Sacks 1998). All the available examples are suggestive of a triggering connection, but quantifying that connection is not straightforward. Linde and Sacks (1998) analyzed the historical record of large earthquakes and explosive eruptions and found that within a day or two of large earthquakes, there are many more eruptions within a range of about 750 km than would otherwise be expected. Therefore, they concluded that eruptions occur in the vicinity of a large earthquake more often than would be expected by chance. Additionally, it is well known that volcanoes separated by hundreds of kilometers frequently erupt in unison; the characteristics of such eruption pairs are also consistent with the hypothesis that the second eruption is also triggered by the earthquakes associated with the first (Linde and Sacks 1998). There is also strong evidence that large earthquakes can affect the unrest condition of volcanoes producing transient enhancement of microseismic and hydrothermal activities as well as ground deformation (see Gasparini 2013).

As for the earthquake-earthquake interactions, several mechanisms have been proposed to

plausibly explain the volcanic eruption triggering by large earthquakes, being the most widely discussed those associated with transient (or dynamic), viscoelastic (or quasi-static), and permanent (or static) stress and strain changes. In fact, earthquakes can stress magmatic systems either through static stresses (e.g., the offset of the fault generates a permanent deformation in the crust), viscoelastic stresses (e.g., a change in the stress state in the elastic crust associated with slow, viscous relaxation of the lower crust and upper mantle beneath the epicenter of a large earthquake), or dynamic stresses from the seismic waves (Hill et al. 2002; Manga and Brodsky 2006).

Dynamic stresses are proportional to the seismic wave amplitude, which is influenced by different factors as directivity, radiation pattern, and crustal structure. However, the significant difference in dependence on distance is a robust feature distinguishing static and dynamic stresses. The difference in decay rate helps to identify which stresses may be important for triggering eruptions. Static stress changes die off rapidly with distance (as $\sim 1/r^3$, with r the distance from the epicenter); therefore, their influence is limited to distances of a few fault lengths (near field). Quasi-static stress changes die off more slowly with distance (as $\sim 1/r$ or $1/r^2$), similarly to the dynamic stress changes that die off as $\sim 1/r$ for surface waves and $\sim 1/r^2$ for body waves (e.g., Hill et al. 2002; Manga and Brodsky 2006).

To provide a comparative example, Table 1 lists the order of magnitude of earthquake stresses

Seismic Risk Assessment, Cascading Effects, Table 1 Static and dynamic stress changes of an M8.0 earthquake at different distances from the source (From Manga and Brodsky 2006)

M8.0 earthquake	Distance from the source		
	Stress (MPa)		
	10 ² km	10 ³ km	10 ⁴ km
Static stress changes	1.0 × 10 ⁻¹	1.0 × 10 ⁻⁴	1.0 × 10 ⁻⁷
Dynamic stress changes	3.0	6.0 × 10 ⁻²	1.0 × 10 ⁻³

Seismic Risk Assessment, Cascading Effects, Table 2 Order of magnitude of other sources of forcing (From Manga and Brodsky 2006)

Phenomena	Stress MPa
Solid earth tides	10^{-3}
Ocean tides	10^{-2}
Hydrological loading	10^{-3} to 10^{-1}
Glacier loading	10^1 to 10^2

at different distances from the source, and Table 2 lists other external stresses that have been also proposed to influence volcanoes (example from Manga and Brodsky 2006). In the near field, both static and dynamic stresses may exhibit significant values; conversely, in the far field only the dynamic stresses are larger than other potential triggering stresses proposed; for instance, for distances greater than 10^3 km, the static stress changes are at least one order of magnitude lower than the other forcing sources presented in Table 2.

Several models have been proposed to explain the different triggering mechanisms. Here we summarize the main examples presented in Hill et al. 2002 and in Manga and Brodsky 2006 (and references therein) for the static and dynamic stress triggering. The reader is invited to consult these references for more detailed information.

Static stress triggering: Static stress changes can be a factor triggering volcanic eruptions at intermediate distances (few hundred kilometers). Explanations for this kind of interaction are based on pressure changes in a magma body induced by the isotropic, compressional component of the stress field in the vicinity of the volcano. Increased compressional stress in the crust surrounding an already fully charged magma chamber may squeeze magma upward. Likewise, a decrease in compressional stress can promote vesiculation, bubble formation, and unclamping of conduits above the magma body (Hill et al. 2002).

Dynamic stress interactions: Several models have been proposed to explain the phenomenon of dynamic triggering by distant earthquakes but the physical processes remain a matter of discussion. Considering in particular those mechanisms in which fluids are active in the triggering

process, examples of the models proposed include (Hill et al. 2002):

- Excitation of bubbles in a gas-saturated fluid by passing seismic waves, which acts to increase fluid pressure through advective overpressure and/or rectified diffusion (see, e.g., Hill et al. 2002; Manga and Brodsky 2006).
- Hydraulic surge, a model in which the seismogenic crust is separated from the underlying plastic crust and an embedded magma body by an impermeable transition zone; a hydraulic surge occurs when the large dynamic strains associated with seismic waves from a large, distant earthquake disrupt the impermeable seal.
- Rupturing blockages in confined aquifers, in which passing seismic waves disrupt blockages in fractures formed by precipitates in a confined aquifer allowing local adjustments in fluid pressure within the aquifer.
- Sinking crystal plume model, in which relatively dense, loosely held masses of crystals can accumulate on the ceiling and walls of a crystallizing magma body and might be dislodged by passing seismic waves. As crystal-rich plumes sink, less dense, crystal-poor magma will be forced upward initiating a convective cycle. Volatiles in the ascending plume will form bubbles and a pressure increase through advective overpressure.
- Relaxing magma body: A magma body may reach a partially crystallized state by either (1) gradual cooling of a previously molten volume or (2) partial melting of a previously solid volume. The solid matrix will partially support accumulating tectonic stresses in the region. Strong seismic waves may disrupt the solid matrix thereby redistributing stress to the surrounding crust as the magma body deforms through viscous relaxation.

Different observations worldwide indicate then that the triggering effect between earthquakes and volcanic eruptions may exist under certain conditions. Stress changes, in particular, seem to be a plausible mechanism capable of triggering volcanic eruptions in a wide range of

distances and times. Given the complexity of the problem and of the interactions, until now the problem is generally treated statistically. New observations in currently well-monitored volcanoes, statistical significance of the correlations, and physics of the triggering mechanisms are important research topics that need to be addressed in order to better constrain this kind of hazard interaction.

Earthquakes Triggering Industrial Accidents

Damages in industrial plants are known to have triggered a number of severe accidents caused mainly by the loss of containment of hazardous substances. Industrial accidents can be triggered by a number of causes, the most common of which are internal system failures and/or human errors (Rasmussen 1995). However, industrial facilities may also be subject to accidents triggered by external factors as natural events. Analyzing different databases of industrial accidents in Europe and the USA, Kraussmann et al. (2011) outlined that between 2 % and 5 % of the recorded accidents were triggered by natural hazards (so-called Natech accidents), being this probably a low bound because of a reporting bias towards accidents with severe consequences.

From the perspective of cascading effects, earthquakes are one of the possible natural hazards triggering Natech accidents. Earthquakes may cause damages in industrial facilities by the direct impact caused by the ground shaking and also by secondary effects as liquefaction. Considering the results presented by Kraussmann et al. (2011), pipework, pipelines, and tanks for the atmospheric storage of chemicals appear to be particularly vulnerable to excitation and damage by the earthquake forces. In the analyzed cases, about 27 % of the accidents presented only structural damages, whereas about 73 % of the cases exhibited damage with release of hazardous materials. These results seem to suggest that chemical equipment is much more likely to suffer damage with loss of containment than not (Kraussmann et al. 2011). Therefore, scenarios of cascading effects with earthquakes as triggering mechanism causing Natech accidents

(because of damages in industrial facilities) can be followed by other triggered hazards as, for example, the release of hazardous materials, explosions, and fires.

A recent outstanding example of cascading effects leading to industrial accidents triggered by earthquakes is the case of the Tohoku earthquake, Japan. On March 11, 2011, the Tohoku-Oki earthquake generated a tsunami 130 km off the coast of Miyagi Prefecture, northeast Japan. The tsunami first reached the Japanese mainland about 20 min after the earthquake and ultimately affected a 2,000 km stretch of Japan's Pacific coast (e.g., Mori et al. 2011). The tsunami caused nuclear accidents, primarily the damages at three reactors in the Fukushima Daiichi Nuclear Power Plant complex. Accounting for all of the factors relevant during the Tohoku disaster, Khazai et al. (2011) analyzed the cascading effects produced by the main earthquake and both the tsunami and the nuclear power plant incidents and produced a causal map depicting the direct and indirect interactions between the various events.

Considering Cascading Effects in the Seismic Risk Assessment

Taking as reference the general concepts described in Eq. 1, in more quantitative terms, risk is often quantified using an expression of the form (e.g., Cornell and Krawinkler 2000; Marzocchi et al. 2012):

$$\lambda(\ell) = \int_D \int_{I_m} \underbrace{F(\ell|D)}_{\text{damgae \& loss}} \underbrace{dG(D|I_m)}_{\text{hazard}} d\lambda(I_m) \quad (4)$$

where $\lambda(I)$ represents a rate of loss, $F(I|D)$ is the probability that a given loss is reached given the damage state D , $G(D|I_m)$ is the vulnerability (or fragility) term, $\lambda(I_m)$ is the hazard, measuring the exceedance rates of given intensity measures (I_m) characterizing the hazard, I is the loss in one specific metric, and D is a given damage state.

Assessing interactions, or cascading effects, in a multi-hazard problem consists on the identification of the possible interactions that are likely to happen and that may result in an amplification of the expected losses in a given area of interest. This process may be performed in the following steps:

1. Identification and structuring of the plausible scenarios of cascading effects
2. Identification of the kind of interactions according to the proposed taxonomy
3. Quantification of the scenarios of interest

Assuming that the value of the exposed elements remains constant in a given time window of interest, the amplification of the losses may be caused by an increase in the occurrence probability of the hazard or by an increase in the probability of damage by a change in the fragility of the exposed elements. In some cases both elements may be considered in a single scenario. In the first case, the analysis of interactions updates the hazard term in Eq. 4; in the second case, the damage term in Eq. 4 is updated.

Identification and Structuring Scenarios of Cascading Effects

An important initial step towards the assessment of cascading effects is the identification and structuring of the possible scenarios. The term “scenario” is used in a wide range of fields and so different interpretations can be found in practical applications. In general, a scenario may be considered as a plausible and consistent representation of an event or series of actions and events. It must be plausible because it must fall within the limits of what might conceivably happen and must be consistent in the sense that the combined logic used to construct a scenario must not have built-in inconsistencies.

Different strategies can be adopted in order to exhaustively identify a complete set of scenarios. In general, they are based on different complementary approaches ranging from event-tree-like to fault-tree-like strategies. In many applications, an adaptive method

combining both kinds of approaches is applied in order to ensure an exhaustive exploration of scenarios. A wide description of practical methods for scenario identification and structuring can be found, for example, in Haimes (2009).

Taxonomy of Interactions

Taking as reference the works of Marzocchi et al. (2012), Garcia-Aristizabal et al. (2013), Selva (2013), and Garcia-Aristizabal et al. (forthcoming-2015), it is possible to define a generalized taxonomy of interactions considering two possible kinds of interactions, namely, (1) interactions at the hazard level, in which the occurrence of a given initial *triggering* event entails a modification of the probability of occurrence of a secondary event and (2) interaction at the vulnerability (or damage) level, in which the main interest is to assess the effects that the occurrence of one event (the first one occurring in time) may have on the response of the exposed elements against another event (that may be of the same kind as the former but also a different kind of hazard). Implicitly, a combination of both kinds of interactions is another possible case; therefore, in the discussion of the interactions at the vulnerability level, both dependent and independent hazards can be considered as possible cases.

Triggering Effects: Interactions at the Hazard Level

In this case, the interaction problem is understood as the assessment of possible “chains” of adverse events in which the occurrence of a given initial *triggering* event entails a modification of the occurrence probability of a secondary event. Even if this typology of problems can be assessed in a long-term basis, their utility can be highlighted in short-term assessments, in which specific scenarios conditioned to the occurrence of given specific events can be assessed and compared among them.

Let us first consider two different threatening events, whose occurrences are E_1 and E_2 . In general, the probability of E_2 occurring (generically hazard H_2) can be written as (Marzocchi et al. 2012):

$$H_2 = p(E_2) \\ = p(E_2|E_1)p(E_1) + p(E_2|\bar{E}_1)p(\bar{E}_1) \quad (5)$$

where, p represents a probability or a distribution of probability and $\bar{E}_1$ means that the event E_1 does not occur. Equation 5 represents the total probability of E_2 occurring considering generically the occurrence or nonoccurrence of E_1 . However, the quantification of risk generally requires the hazard assessed in function of a specific intensity measure (IM) characterizing the hazard, and therefore Eq. 5 can be generalized in order to consider the specific contribution of different IM values. Therefore, the occurrence of the triggered event 2 (E_2) given the occurrence of the triggering event 1 (E_1) representing this kind of interaction can be assessed as (Garcia-Aristizabal et al. 2013):

$$p(\geq IM_2^i) = \sum_j p(\geq IM_2^{i,j}) \quad (6)$$

that explicitly conditioned to E_1 can be written as (e.g., Garcia-Aristizabal et al. 2013; Selva 2013; Garcia-Aristizabal et al. forthcoming-2015):

$$p(\geq IM_2^i) = \sum_j p(\geq IM_2^i | IM_1^j) p(IM_1^j) \quad (7)$$

For $j = 1, 2, 3, \dots, n$, for the n (exhaustive and mutually exclusive) classes of IM defined for the triggering event. IM_1 is the intensity measure defined for the triggering event, and IM_2 is the intensity measure defined for the triggered event. Note that Eq. 7 is a generalization of Eq. 5. A key element in this formalization is $p(\geq IM_2^{i,j})$, which we call the *interaction term*. When $i > 1$ and $j > 1$, $p(\geq IM_2^{i,j})$ is represented by a $i \times j$ matrix that defines a probability surface, as shown in Fig. 4. When $i = 1$ or $j = 1$, $p(\geq IM_2^{i,j})$ is a row or column vector, and in the hypothetical limit case in which the problem does not consider the intensity measures of both the triggered and triggering events, the problem is simplified as the case described by Eq. 5 (i.e., considering the “occurrence” and “nonoccurrence” of the event 1). Considering, for example, the earthquake-triggered landslide case, the earthquake is represented by E_1 and the triggered landslides are the E_2 ; IM_1 can represent the ground-motion intensity and IM_2 the volume of the mass sliding. Therefore, $p(\geq IM_2^i | IM_1^j)$ represents the probability of exceeding a given sliding mass volume given a certain ground shaking intensity, and $p(\geq IM_2^i)$ represents the *total* probability of exceeding a given sliding mass volume considering the full range of possible ground shaking intensities taken into account from the triggering earthquake hazard.

Seismic Risk Assessment, Cascading Effects, Fig. 4 Probability surface represented by $p(\geq IM_2^{i,j})$, for $i > 1$ and $j > 1$

Additive Effects of Different Events: Interactions at the Vulnerability Level

This perspective of the cascading effect problem fundamentally intends to assess the effects that the simultaneous occurrence of two or more events (not necessarily linked among them) may have for the final risk assessment. In this case, the action of different hazards is considered and combined at the vulnerability (or damage) level, and the main interest is to assess the effects that the occurrence of one event (the first one occurring in time) may have on the response of the exposed elements against another event (that may be of the same kind as the former but also a different kind of hazard). Examples of this kind of interactions have been presented in literature, for example, in Lee and Rosowsky (2006), Zuccaro et al. (2008), Marzocchi et al. (2012), Garcia-Aristizabal et al. (2013), and Selva (2013).

In practice, the idea in this case is to quantify how the expected damages in the target area (caused by a given hazard) can be modified if another hazardous event acts on the exposed elements simultaneously or in a short-time window (in general short enough that the system cannot be repaired). In the case of two hazards having additive load effects (i.e., they act simultaneously over the exposed element), the fragility function will depend on the intensities IM_1 and IM_2 of the two hazards, and then it will represent a fragility surface. The probability that a given damage state (D_k) is reached given the occurrence of the i -th value of IM_1 and the j -th value of IM_2 can be represented as (for details see Lee and Rosowsky 2006; Garcia-Aristizabal et al. 2013; Selva 2013):

$$p(D_k) = \sum_i \sum_j \left[P(D_k | IM_1^i \cap IM_2^j) p(IM_1^i \cap IM_2^j) \right] \quad (8)$$

The conditional probability $P(D_k | IM_1^i \cap IM_2^j)$, hereinafter referred to as $P(D_k | IM_1^i, IM_2^j)$ for simplicity, is the probability that the damage state D_k is reached at given levels of loads IM_1 and IM_2 (due to hazard events 1 and 2, respectively) acting simultaneously. Therefore, to calculate $p(D_k)$

considering any value of the IM of the events 1 and 2, we need to consider two cases, namely, (1) when events 1 and 2 are independent and (2) when there is dependence between events 1 and 2.

Independent Events In the simpler case, we consider the two hazards as independent events, in the sense that the occurrence of one does not change the probability of the other occurring. In that case, the probability that a given damage state is reached for all the possible values of IM_1 and IM_2 can be defined as (e.g., Garcia-Aristizabal et al. 2013):

$$p(D_k) = \sum_i \sum_j \left[P(D_k | IM_1^i, IM_2^j) p(IM_1^i) p(IM_2^j) \right] \quad (9)$$

which is an expression coherent with the framework defined by Lee and Rosowsky (2006) analyzing the effects of the combined seismic and snow loads on wood structures. In this case, the fragility function $P(D_k | IM_1^i, IM_2^j)$ will represent a probability surface as that shown in Fig. 5. The example presented in Fig. 5 shows the combined effect of seismic (in pga) and volcanic ash (in Kpa) loads acting simultaneously on roof structures in Naples, Italy. The data used to generate this figure was derived from the work presented in Zuccaro et al. (2008).

Dependent Events If the occurrence of one event (E_1) does affect the probability of the other occurring (E_2), then the events are dependent. This is the case described in the interactions at the hazard level. In this case, the term $p(IM_2^j \cap IM_1^i) = p(IM_2^j | IM_1^i) p(IM_1^i)$ and then the probability that a given damage state D_k is reached for the case of dependent events can be defined as:

$$p(D_k) = \sum_i \sum_j \left[P(D_k | IM_2^j, IM_1^i) p(IM_2^j | IM_1^i) p(IM_1^i) \right] \quad (10)$$

In this case, $P(D_k | IM_2^j, IM_1^i)$ is again a fragility surface as that represented in Fig. 5, and the

Seismic Risk

Assessment, Cascading Effects, Fig. 5

Fragility surface for the case of seismic and volcanic ash acting simultaneously on the roofs in Naples, Italy (Derived from the data in Zuccaro et al. 2008). Note that when the ash load tends to zero, the fragility function converges towards the pure seismic fragility

hazard term takes into account the possible dependence between events 1 and 2. For example, considering again the earthquake-triggered landslide case, assessing the “collapse” damage state would require the fragility surface $P(D_k | IM_2^l, IM_1^l)$ for assessing the probability of collapse given the combined effect of the ground shaking intensity (IM_1) and, for example, the depth of the deposit caused by the mass movement (IM_2). On the other hand, the hazard term in this case would be calculated as shown in the example presented for the *interactions at the hazard level*, in which the probability of exceeding a given IM_2 value is assessed considering the full range of likely intensities of the triggering ground motions caused by the earthquakes.

Damage-Dependent Vulnerabilities in Cascading Effects

The damage-dependent vulnerabilities (or fragilities) can be considered as a special case of the interaction at the vulnerability level. In fact, the development of fragility surfaces, as presented in the previous section for that kind of interactions, is intended for general cases in which the additive effect of different loads may act simultaneously over the exposed element, which does not necessarily imply a pre-damage of the element. For example, the action of the first occurring hazard

may just result in a modification of the response of the exposed element (e.g., a structure) to another typology of hazard without causing a permanent deformation or damage that remains in time. Examples of this case can be snow or volcanic ash deposited over a roof; this extra weight in the structure may cause it to behave differently if it is shaken by the ground motion caused by an earthquake (compared with the normal structure’s behavior). However, in many cases this interaction may imply that the first acting event produces permanent deformations in the structure (i.e., causing some damages) implying some modification to its response to new solicitations and the need to develop damage-dependent fragility functions.

The most frequent development of damage-dependent fragility functions is found for seismic loads (i.e., to assess the structure’s response to new earthquakes after it has been damaged by the past earthquakes). Different works tackling the problem of the response of structures pre-damaged by earthquakes can be found in literature and mainly associated with the assessment of post-mainshock time-dependent risk. Examples can be found in (Bazzurro et al. 2004; Yeo and Cornell 2005; Ryu et al. 2011; Luco et al. 2011) and references therein. In general, the fragility curves used for the post-mainshock

risk assessment accounts for any damage caused by the mainshock. This typically increases the probabilities of collapse for the considered range of potential (future) IM values, and the amount of increase depends of course on the extent of the mainshock damage, which is commonly discretized into damage states (DS) as, for example, none, slight, moderate, extensive, and complete (Luco et al. 2011). Following Ryu et al. (2011, and references therein), the fragility for a mainshock-damaged structure can be computed as:

$$p(D_a > d_a | IM_a = im_a, D_m = d_m) \\ = \int P(D_a > d_a | IM_a = im_a, EDP_m = edp_m) \times \\ f(EDP_m = edp_m | D_m = d_m) dedp_m \quad (11)$$

where D_a represents the post-aftershock damage state, D_m represents the post-mainshock damage state, EDP_m , the engineering demand parameter (e.g., drift), represents the mainshock building response, and IM_a represents the ground-motion intensity of an aftershock (Ryu et al. 2011). The first term in Eq. 11 can be computed using the fragility for the intact building or that for a mainshock-damaged building whose mainshock response (EDP_m) is edp_m . The second term in Eq. 11 can be computed using the assumed distribution of mainshock response given post-mainshock damage state (for details see Ryu et al. 2011; Luco et al. 2011).

Summary

Different past disasters have highlighted the fact that natural or man-made events can trigger other events, leading to a non-negligible increase of fatalities and damages. As a consequence, there is an increasing interest on implementing multi-type hazard and risk assessments as well as assessing cascading effects, which are one of the fundamental concepts of the multi-risk assessment. As for most of the quantitative risk assessment for natural hazards, the seismic risk assessment is generally carried out separately

without considering the effects of possible chains of events triggered by earthquakes. From the risk assessment point of view, the cascades of events occurring after an earthquake may represent a non-negligible source of loss amplifications. For quantitative purposes, we can consider the cascading effects analyzing two major sets of interactions: (1) interactions at the hazard level and (2) interactions at the vulnerability level. In this entry we present and discuss different examples of scenarios of cascading effects triggered by earthquakes.

Seismic Robustness Analysis of Nuclear Power Plants

Introduction

Nuclear Safety

Commercial nuclear power plants (NPP) are industrial facilities that represent a significant hazard potential. Consequently, the pertinent safety requirements are particularly stringent. Nuclear safety is assured by deterministic and probabilistic analysis. In deterministic analysis, the safety systems are shown to withstand design basis accidents (DBAs), typically using conservative assumptions. In probabilistic safety analysis (PSA), the frequency of accident progressions leading to core damage (PSA level 1) and large

early release (PSA level 2) is quantified and compared to target values that are judged as low enough.

Consideration of Earthquakes in Nuclear Safety

Earthquakes are external hazards on which the duty holder of a nuclear facility, e.g., a nuclear power plant, has no or only little control.

Effects to be expected at a site from an earthquake especially include vibrations induced in structures, systems, or components (SSC) through the civil structures of the plant. These vibrations could affect the plant safety functions directly, e.g., when the induced seismic loads would exceed the capacity of safety relevant equipment items. Indirect failure modes such as mechanical interaction, dropped loads, release of hazardous substances, seismic-induced fire or flooding, impairment of operator access, or unavailability of evacuation and access routes may also be of concern (see IAEA 2003a, §2.11).

Current design practice for a nuclear facility ensures an adequate seismic design from a deterministic perspective.

A safe shutdown earthquake (SSE) is selected based on the results of a seismic hazard analysis of the site. The SSE represents a site-specific extreme seismic event. The attribute “extreme” is justified because the SSE is defined so conservatively that it can be expected with a very high level of confidence that it will not be exceeded during the operational lifetime of the plant. SSCs necessary to transfer the plant into a safe shutdown state are identified and designed to remain functional under SSE loading. Similarly, SSCs whose seismic-induced failure could lead to interaction effects on safety equipment are identified and designed for integrity or stability as required by safety analysis. The demonstration that the design requirements are met consists in mechanical analysis or shaking table testing of the selected systems, structures, and components (SSC), subject to vibrations induced by the SSE.

The described provisions ensure that even in the case of an extreme seismic event, represented by the SSE, the main safety functions (reactivity

control, residual heat removal, confinement of radioactive substances) are met.

Motivation for Evaluating Seismic Robustness

What was described above is – in very simplified terms – the procedure for ensuring a safe initial design of an NPP, as far as seismic loads are concerned. Besides that, nuclear safety is also concerned with ensuring continuously that it is safe to operate the plant, e.g., by means of periodic safety evaluations or if new insights are gained.

Indeed, during the plant's lifetime, new information becomes available which may challenge the initial design basis of the plant. This new information may especially be of seismological nature (e.g., newly discovered seismogenic structures, newly installed seismological networks, new paleoseismological evidence or actual occurrence of damaging earthquakes in the site vicinity). However, there may also be new technical findings such as the indication that certain SSC may be more vulnerable than initially expected (see IAEA 2009, §2.10).

In consequence the nuclear industry and regulatory authorities are frequently faced with the question whether these changes can be accommodated within the seismic capacity of the original design or whether modifications are necessary to maintain an adequate level of safety (see ASCE 2000, p. 41).

When assessing the safety of a nuclear facility, the plant performance in seismic events exceeding the ground motion characteristics of the SSE (typically associated with mean return periods ≤ 10.000 years, see below) is also of interest. See, for example, §2.39 in IAEA (2003a): *“Seismic design should be carried out [...] to provide margins for seismic events that are beyond the design basis and to prevent potential small deviations in plant parameters from giving rise to severely abnormal plant behaviour ('cliff edge' effects). [...]”*

Last but not least, the severe accidents which occurred at Japan's Fukushima-Daiichi plants in response to the Great Tohoku Earthquake of March 2011 have stimulated an increased

interest in studies quantifying the actual margin of failure (“Seismic Margin Assessment” – SMA) or providing an insight into the risk associated to earthquakes (“Seismic Probabilistic Safety Analysis” – SPSA, often also referred to as “Seismic Probabilistic Risk Assessment” – SPRA).

Seismic Hazard Assessment

Before introducing the two main approaches for assessing the robustness of NPPs, it is necessary to briefly introduce the notion of seismic hazard.

The assessment of the site-specific seismic hazard – i.e., the characterization of the ground motions to be “expected” at a particular site – is a critical ingredient of both the (initial) design against seismic loads and periodic safety reviews during the plant's lifetime.

Seismic events are unpredictable (stochastic) as far as three of their most basic characteristics are concerned: timing, i.e., when they occur; magnitude; and location of the epicenter. The unpredictability of the latter two properties implies that the ground motion characteristics are also unpredictable. As in many fields of science and engineering, the difficulties associated with the unpredictability can be alleviated – to some extent – by adopting a probabilistic approach: indeed the unpredictability is confined to individual realizations of the stochastic phenomenon, whereas ensemble properties (statistics) are now predictable.

For the purpose of NPP safety, the results of a seismic hazard assessment are essentially pairs of data. Each pair consists of:

- One data item characterizing ground motion (such as the peak ground acceleration, or a response spectrum)
- One data item characterizing how rare it is to observe an event leading to such a ground motion (e.g., return period or annual probability of exceedance)

The latter data item is typically governing the specification of seismic loads. The annual probability of exceedance is prescribed at an

adequately low level, which varies from country to country; typical values of this probability are $10^{-4}/a$ and $10^{-5}/a$. The corresponding ground motion then represents the SSE.

The need to characterize events with extremely low probabilities of exceedance introduces an obvious data problem, as there cannot be – by definition – direct observations within the range of interest. Extensive efforts – which are far beyond the scope of this essay – have been ongoing for decades in order to predict extreme seismic events, mainly by modeling the processes from the source to the origin, i.e., the source mechanisms, the propagation (attenuation), and the site response. For an overview and further reading on seismic hazard refer, for example, to Chen and Scawthorne (2002). The level of uncertainty associated with these models – both due to limited observations for calibrating the model and due to the existence of concurrent models – remains very high.

This large degree of uncertainty associated with seismic hazard estimates is also one of the main reasons for the significant interest in the seismic robustness.

Two Approaches for Quantifying Seismic Robustness

There exist essentially two approaches for quantifying the robustness of NPPs to seismic-induced ground motions, namely, seismic margin assessment (SMA) and seismic probabilistic safety analysis (seismic PSA). It should be noted that in the United States, the term “probabilistic risk analysis” (PRA) is used instead of PSA.

In **SMA** the robustness is determined **explicitly** in terms of the margin between the design acceleration, used for determining the seismic loads on structures and equipment in the design calculations, and the plant capacity, i.e., the limit load that the plant can at most sustain and hence still be brought to a safe state and maintained in that state.

In contrast, in **seismic PSA** the margin is not quantified explicitly. Rather, for a comprehensive range of characteristic ground motions of increasing severity, the corresponding probability of

a core damage is evaluated. Core damage is mainly defined as the failure to meet the core cooling criteria and the associated overheating of the fuel rod cladding.

By taking into account the frequency of occurrence of the characteristic ground motions – expressed by the so-called hazard curve – and the corresponding core damage probabilities, one obtains a concise measure of the seismic risk in the form of the seismic-induced core damage frequency. In this quantity, the robustness is **implicitly** contained. Indeed, for a given hazard curve, a plant with a larger margin will have a smaller core damage frequency than a plant with a smaller margin.

Conversely, the opposite can be said about the methods as far as the notion of risk is concerned: in SMA the risk is contained implicitly, whereas the result of seismic PSA is an explicit expression of risk.

In both approaches – SMA and seismic PSA – the focus is on the **plant-level** robustness, i.e., it is essential that the safeguard systems of the plant be able to fulfill their safety function, even if individual equipment items may have failed. The analysis of the plant-level robustness takes into account the multiple lines of defense and the safety concepts – such as redundancy and diversity – implemented in the engineered safeguards. Ultimately, however, the plant-level robustness can be traced back to the seismic margin of **individual** systems, structures, and components (SSC). Hence, before discussing seismic robustness in terms of plant-level safety functions, the concept of seismic margin is introduced for individual SSC.

Seismic Margin of Systems, Structures, and Components

Load Versus Capacity

Considering the deterministic approach applied for the seismic design of nuclear facilities, a straightforward approach to quantify seismic margins would be to compare (for each important SSC) the load experienced by the SSC in case of

Seismic Robustness Analysis of Nuclear Power Plants,

Fig. 1 Margin definition in terms of seismic load

SSE with the load capacity, i.e., with the maximum load the SSC can still handle without failing to meet its requirements (stability, integrity, or operability) (Fig. 1).

However, a statement like “the mechanical analysis of the control rod drive mechanism reveals a seismic margin of x kN” would not be a very comprehensive expression of the existing margin, because it looks only at the quantities in the final step of the analysis chain that needs to be undergone in the seismic design of typical NPP equipment. Indeed, for the standard equipment item, the mechanical analysis is preceded – at least – by the analysis of the response of the floor on which the equipment is mounted.

The above statement is hence an incomplete estimate of the margin, because it neglects additional margins accumulated in the previous links of the analysis chain, such as the dynamic analysis of the civil structures.

Furthermore, it would not be a suitable basis for comparing the margins of different components relative to each other. For these reasons, it has proved useful to define the margin in terms of one characteristic ground motion parameter.

Expressing Margins in Terms of Ground Motion Parameters

Typically an SSE is defined by free-field ground motion response spectra. Seismic margin above the SSE is then most commonly quantified in terms of one parameter representative of the ground response spectra, the peak ground acceleration (PGA) being the most frequently used parameter. Alternative parameters are, e.g., the

peak spectral accelerations or the intensity on the Medvedev–Sponheuer–Karnik (MSK) scale. Frequently, the use of PGA as the representative parameter for expressing seismic margin and seismic fragility is criticized, on the grounds that it is a poor indicator of structural damage. Nevertheless, the PGA has gained the broadest acceptance as the characteristic margin parameter, probably due to its simple physical interpretation that can be grasped also by decision makers not familiar with more sophisticated notions of earthquake engineering or seismology (refer to IAEA 2003b, p. 6).

It should be noted that there are ways for compensating the limitation of PGA as a unique descriptor of a seismic event, either on the hazard definition – relying on notions such as the intensity or cumulative absolute velocity (CAV; refer to EPRI (2006), Campbell and Bozorgnia (2011)) in the hazard curve development – or on the structural response (→spectral shape factor in the fragility definition below).

Variability Due to Randomness and Uncertainty

The load to which an SSC is subjected during an earthquake of a certain PGA is clearly nondeterministic: indeed, there are an infinite number of possible ground motions showing the same PGA, each of which would induce different loads. This inherently aleatory characteristic of seismic ground motions is denoted as randomness.

Moreover, the majority of safety-related SSC is not directly subjected to ground motion but to vibrations induced through the plant’s civil

Seismic Robustness Analysis of Nuclear Power Plants,
Fig. 2 Nondeterministic character of load demand and capacity

structures. Thus, there is nondeterminism – both inherent (randomness) and epistemic (uncertainty) – associated to effects like soil-structure interaction, damping, load combination, etc. Finally, also the load capacity is nondeterministic, considering, e.g., that material properties cannot be fully controlled.

The nondeterministic character of both load demand and seismic capacity is typically modeled by random variables, as illustrated in Fig. 2.

Seismic failure will occur when the load demand D exceeds the capacity C ; the probability of failure P_F is then

$$P_F = P(D > C)$$

In view of the clearly nondeterministic nature of load demand and capacity, a conceptually sound definition of margin must be formulated in a probabilistic framework. A concept that has found widespread acceptance for this purpose is the definition of a HCLPF (pronounced as “hay-clipf”) capacity. It is an implicit definition: if a component has a HCLPF capacity of x , then the probability of failing due to a demand of value x is low (5 %), with a high confidence (95 %). For the reasons stated in the previous section, the parameter in terms of which the HCLPF capacity is typically defined is the PGA.

Having captured the nondeterministic nature of the quantities governing failure, by means of the HCLPF capacity, it is now straightforward to quantify margin, e.g., as the distance between the HCLPF capacity and the load demand prescribed in the design of the NPP (i.e., the SSE).

More details on the HCLPF concept, including the approaches for its quantification in practical problems, are presented in section “Sources of Seismic Margin” below.

Sources of Seismic Margin

In principle seismic margin could be introduced on a deterministic basis specifying design basis loads exceeding those determined for the SSE or introducing penalizing stress utilization criteria. However, an overly conservative approach would induce significant extra cost in the entire life cycle of the plant (equipment design and procurement, civil construction, maintenance of heavy equipment items, decommissioning, etc.) and possibly detrimental effects on SSC performance in normal plant operation. In practice there are already various conservatisms in the seismic design of SSC. These conservatisms can be assessed and quantified when performing an SMA or an SPSA to show that adequate margin is available. Seismic margin especially results from the following sources:

- *Definition of the safe shutdown earthquake:*
 SSE ground motion response spectra are enveloping design spectra, i.e., the spectra have usually been subject of smoothing and broadening. In particular this introduces a substantial artificial increase of energy content of the excitation.
- *Conservatism in the determination of the seismic demand:*
 Earthquakes induce oscillations of a chain of different oscillators at a site: starting from

**Seismic Robustness
Analysis of Nuclear
Power Plants,**

Fig. 3 Earthquakes and their impact on civil structures and equipment (Translated from Sadegh-Azar and Hartmann 2011)

the soil, the base plate, and the upper floors of buildings up to smaller pieces of equipment installed in instrument racks or connected to flexible piping (Fig. 3). These different oscillating subsystems show more or less significant interaction effects; for example, the heavy weight of the reactor building has a damping effect on ground oscillations. Similarly heavy equipment installed inside the containment has a damping effect on the vibrations of the supporting floors. A realistic description of this complex oscillation behavior would therefore require modeling the entire system and considering also nonlinear effects such as plastic deformation.

Since such a global analysis is usually not practicable, the overall system is normally split into several subsystems analyzed separately. The following example illustrates this approach:

Subsystem	Excitation	Response
Ground + buildings	Ground response spectrum and corresponding time histories	Floor response spectra (secondary spectra) and corresponding time histories
Large equipment (e.g., primary circuit), civil substructures	Floor response spectra (secondary spectra) and corresponding time histories	Tertiary spectra and corresponding time histories
Equipment (e.g., pipes)	Tertiary spectra and corresponding time histories	Quaternary spectra and corresponding time histories
Built-in components (e.g., valve)	Quaternary spectra and corresponding time histories	Loads

Such an approach induces several sources of conservatism:

- Excitation characteristics and physical parameters considered for the different models are chosen conservatively to ensure that the conclusions made are valid without high uncertainty. The resulting level of conservatism may be moderate considering one model only. However, combining several models in a calculation chain, these conservatisms are multiplied and result typically in high factors of safety.
- Especially with respect to input characteristics, bounding assumptions are typically made. For example, many relevant codes require smoothing, broadening, or even increasing of input spectra. Similarly, the combination of load cases which can physically not occur simultaneously is often applied for the sake of simplification. Finally, the orthogonal vibration components are typically combined in a conservative manner.
- Interaction effects and in particular damping effects between the subsystems are neglected. The resulting conservatisms are especially important if the substructure is excited with a frequency near its resonance frequency, i.e., when the resulting vibrations are most important.
- Realistic anchorage characteristics allowing small displacements - significantly influencing the vibration behavior of the anchored system (shifting of natural frequencies) and thus avoiding resonant situations - are neglected.
- Other nonlinear effects such as plastic deformation and friction are typically also not modeled, and the corresponding energy dissipation is neglected or considered with simplified approaches only.
- *Conservatisms in the determination of the resistance to seismic loads:*

These conservatisms result especially from:

- Application of safety factors following the relevant codes.
- Use of conservative material properties (typically 95 % fractiles are used). In case of civil structures, the time-dependent concrete strengthening is normally also neglected.
- Neglecting plastic deformation capability.
- Finally, seismic margin results from stress utilization < 1 , i.e., if the resulting stresses are smaller than the code allowable stresses. This is particular true when seismic loads are not the governing loads for an SSC.

Quantification of Seismic Margin: Fragility Curves and HCLPF Values

Capacity and Fragility

In order to quantify the abovementioned sources of conservatism and derive an expression of the overall margin, the concept of seismic fragility as introduced by Kennedy and Ravindra (1984) has proven useful.

Seismic fragility is defined as a conditional failure probability, where the condition is represented by a seismic event with a given value of the characteristic ground motion parameter, denoted by a . In the sequel it will be assumed that this ground motion parameter is given by the peak ground acceleration, i.e., the zero period acceleration in the ground response spectrum. In this case the fragility is defined as follows:

$$Fr(a) = P[\text{failure} | PGA = a]$$

The definition of fragility is flexible in the sense that the meaning of the term *failure* is arbitrary. In the context of seismic PSA, it relates mainly to components of safety-relevant systems or to structures in which such components are installed; the entire set of these components and structures is abbreviated as SSC (systems, structures, and components). Quantitatively, failure

occurs if one of the parameters representing the loads experienced by the analyzed SSC exceeds its limit state (e.g., the tensile stress in a reinforcement bar exceeds the tensile strength of the utilized steel). The definition of the limit states for an SSC requires the identification of the relevant failure modes.

It is useful to express the fragility in terms of a random variable representing the capacity, denoted by A , and defined in terms of the same ground motion parameter used for the fragility definition. Obviously, failure occurs if the capacity is lower than the peak ground acceleration of the assumed seismic event. The definition of the fragility can then be extended as follows:

$$Fr(a) = P[\text{failure} | PGA = a] = P[A < a] \\ = F_A(a)$$

The right portion of the above equation emphasizes that the fragility is equivalent to the cumulative density function of the capacity A . This implies that defining the random capacity A is equivalent to defining the fragility.

Log-Normal Capacity Model

The most widely used model for the seismic capacity is given by

$$A = \tilde{A} \varepsilon_R \varepsilon_U$$

where $\tilde{A}$ is the median of the capacity, while ε_R and ε_U are log-normally distributed with unit median and logarithmic standard deviations of β_R and β_U , respectively. The random variables ε_R and ε_U model the variability due to randomness and due to uncertainty, respectively. In order to preserve the distinction between these two different sources of variability, the variables ε_R and ε_U are introduced in two distinct steps of the analysis. To begin with, it is assumed that only the variability to randomness exists, whereas there is no variability due to uncertainty, i.e., $\varepsilon_U = 1$.

At this stage, the fragility is then (due to the properties of the log-normal distribution of ε_R)

$$Fr(a) = \Phi \left(\frac{\ln \left(\frac{a}{\tilde{A}} \right)}{\beta_R} \right)$$

where Φ is the standard normal cumulative distribution function.

In the second step of the fragility analysis, the assumption that $\varepsilon_U = 1$ is relaxed. Instead, ε_U is assumed to be log-normally distributed with logarithmic standard deviation β_U .

Rewriting the capacity as

$$A = \tilde{A} \varepsilon_R \varepsilon_U = (\tilde{A} \varepsilon_U) \varepsilon_R$$

and replacing $\tilde{A}$ with $\tilde{A} \varepsilon_U$ in the cumulative probability density leads to

$$Fr(a) = \Phi \left(\frac{\ln \left(\frac{a}{\tilde{A} \varepsilon_U} \right)}{\beta_R} \right)$$

Due to the presence of ε_U , the fragility at a given PGA a itself turns also into a random variable. It can be shown that for a given probability level Q , the fractile of this random variable is

$$Fr(a, Q) = \Phi \left(\frac{\ln \left(\frac{a}{\tilde{A}} \right) + \beta_U \Phi^{-1}(Q)}{\beta_R} \right)$$

Interpreting Q as a subjective probability, or equivalently as a confidence level, one may use the above equation to obtain the fragility curves associated with specific confidence levels. This is demonstrated in Fig. 4 for the fragility model with the parameters $\tilde{A} = 0.5$ g, $\beta_R = 0.3$, and $\beta_U = 0.4$.

The median (50 % confidence level) fragility curve is identical to the one obtained by neglecting uncertainty (i.e., $\beta_U = 0$).

Seismic Robustness Analysis of Nuclear Power Plants,

Fig. 4 Example of fragility curve in linear scale

The mean fragility curve is obtained by averaging over the random fragility $F_A(a)$ for each value of the ground motion parameter a , i.e., the averaging is done along the vertical direction.

It can be shown that the mean fragility has the following simple form

$$F_A(a) = \Phi \left(\frac{\ln \left(\frac{a}{A} \right)}{\beta_C} \right) \quad \beta_C = \sqrt{\beta_R^2 + \beta_U^2}$$

The above model is called the **composite fragility model**, because it considers random variability and variability due to uncertainty in a compact form. It is used for point estimates (best estimate) of the seismic risk.

Methods for Deriving Fragility Curves of SSC

For the quantification of seismic fragility, one can generally distinguish between approaches relying on the assessment of conservatism in **existing** seismic verification studies and approaches requiring **new** dynamic analyses.

For cost reasons, where possible, preference is given to the former. Within this category, the most widely used approach for deriving fragility

curves is based on **separation of variables**, as described in detail in Kennedy and Ravindra (1984) and in EPRI (1994).

The basic concept underlying this approach is the following expression for the capacity A as a product of the (deterministic) value of the PGA, a_{SSE} , adopted in the seismic design of the SSC under consideration, and the scaling factor F :

$$A = a_{SSE} \cdot F$$

The scaling factor F may hence be viewed as the maximum scalar, by which the design ground motion can be multiplied ("scaled") without producing failure. Alternatively, the factor F may however also be viewed as a safety factor, considering that it is the ratio between the actual capacity A and the acceleration used in the design, a_{SSE} :

$$F = \frac{A}{a_{SSE}}$$

It should be noted that the scaling (safety) factor F is a random variable, since the capacity A is also a random variable.

The essence of the separation of variables approach is to break down the scaling (safety) factor F into a product of “partial” safety factors. This factorization process extends over two levels, since some of these partial safety factors are yet again factorized.

For structures, the factor of safety F can be modeled as the product of three random variables:

$$F = F_S F_\mu F_{RS}$$

where F_S is the strength factor, F_μ is the inelastic energy absorption factor, and F_{RS} is the structural response factor.

The strength factor, F_S , represents the ratio of ultimate strength (or strength at loss of function) to the stress calculated for a_{SSE} . In calculating the value of F_S , the non-seismic portion of the total load acting on the structure is subtracted from the strength as follows:

$$F_S = \frac{S - P_N}{P_T - P_N}$$

where S is the strength of the structural element for the specific failure mode, P_N is the normal operating load (i.e., dead load, operating temperature load, etc.), and P_T is the total load on the structure (i.e., sum of the seismic load – due to a_{SSE} – and the normal operating load).

The inelastic energy absorption factor (ductility factor), F_μ , accounts for the fact that an earthquake represents a limited energy source, and many structures or equipment items are capable of absorbing substantial amounts of energy beyond yield without loss of function.

The structural response factor, F_{RS} , is based on the recognition of the fact that in the design analyses, structural response is computed using specific (often conservative) deterministic response parameters for the structure. Since many of these parameters are nondeterministic (often with wide variability), the actual response may differ substantially from the calculated response for a given peak ground acceleration. F_{RS} is modeled as a product of factors influencing the response bias and variability:

$$F_{RS} = F_{SA} F_{GMI} F_\delta F_M F_{MC} F_{EC} F_{SSI}$$

where:

F_{SA} = spectral shape factor representing bias and variability in ground motion and associated ground response spectra

F_{GMI} = ground motion incoherence factor that accounts for the fact that a traveling seismic wave does not excite a large foundation uniformly

F_δ = damping factor representing bias and variability in response due to the difference between actual damping and damping assumed in design

F_M = modeling factor accounting for limitations regarding the resolution and calibration of the model adopted for representing the structural mechanics

F_{MC} = mode combination factor accounting for bias and variability in the estimated response due to the method used in combining dynamic modes of response

F_{EC} = earthquake component combination factor accounting for bias and variability in response due to the method used in combining earthquake components

F_{SSI} = factor that accounts for the effect of soil-structure interaction

Similarly, for equipment and other components, the overall factor of safety is composed of a capacity factor, F_C ; a structure response factor, F_{RS} ; and an equipment response (relative to the structure) factor, F_{RE} . Thus,

$$F = F_C F_{RE} F_{RS}$$

The individual safety factors F_i are assumed to follow a log-normal distribution. Their characteristic parameters are their median values F_i – representing the (often conservative) **bias** – and the logarithmic standard deviations $\beta_{i,R}$ and $\beta_{i,U}$, representing the **variability** due to aleatory and epistemic nondeterminism, respectively. The most widely used method for estimating these characteristic parameters is the approximate second moment procedure.

The overall median safety factor $\widetilde{F}$ may be found by scaling the ground response spectrum so long, until the limit state corresponding to the analyzed failure mode is reached. All input variables must be set to their median values in this process for the scaling factor to correspond to the median safety factor.

Alternatively, the sources of conservatism of the design calculations – compared to median-centered calculations – may be identified individually for each partial safety factor. For each of the response factors, the response quantity of interest (e.g., stress) is calculated (or estimated) anew, but only with the corresponding input variables set to their median values. The ratio of this newly computed response with the one from the design calculations gives the corresponding median partial safety factor. For the median capacity factor, the margin between the median strength and the stress obtained in the design calculation is quantified. The overall median safety factor is then simply given by the product of the individual safety factors.

In order to estimate the logarithmic standard deviations $\beta_{i,R}$ and $\beta_{i,U}$, it is necessary to perform an additional calculation of the safety factor, in which all model variables are median centered, with the exception of the input variables corresponding to the analyzed partial safety factor. The latter ones are instead perturbed by a multiple κ of their standard deviation. The input variables should be perturbed to the side which leads to a smaller safety factor (since we are more interested in quantifying the effect of variables in the more unfavorable cases). The resulting partial safety factor is denoted here as $F_{\kappa\sigma_i}$.

The variability parameter (either randomness or uncertainty) of the analyzed safety factor is then

$$\beta_i = \frac{1}{|\kappa|} \ln \left| \frac{F_{\kappa\sigma_i}}{\widetilde{F}} \right|$$

For several safety factors it is common practice to use generic variability parameters, as suggested in EPRI (1994).

Finally, the logarithmic standard deviations of the individual safety factors are combined using square root of sum of squares (SRSS), in order to obtain the corresponding variability parameter of the global safety factor, β_R and β_U , respectively.

Alternative, more refined methods can be used for deriving fragility curves, if necessary. For instance, the simplifying assumptions adopted in the separation of variables method can be relaxed by applying Monte Carlo simulation to the structural dynamic analysis. In this method, all parameters assumed to contribute significant nondeterminism to the overall capacity are sampled simultaneously, and the model used for structural dynamic analysis is perturbed correspondingly. Repeating this exercise for several levels of the PGA leads to a discrete set of points of the fragility curve, which can be interpolated or extrapolated as needed.

The HCLPF Capacity

As already indicated in earlier sections, the HCLPF value or HCLPF capacity is a crucial concept in the context of seismic robustness of NPPs. It is defined – implicitly – as the value of the PGA for which there is a *high confidence* (95 %) that the *probability of failure* does not exceed 5 % (i.e., it is *low*).

Based on the above definition, the HCLPF capacity can be related to the median capacity and the variability parameters as follows:

$$HCLPF = A_m \exp(-1.65(\beta_R + \beta_U))$$

where -1.65 is the 5 % fractile of the standard normal distribution.

The HCLPF capacity can be approximated by the 1 % fractile of the composite mean fragility curve. This definition of the HCLPF in the composite model is conservative, because it is guaranteed to be equal or smaller than the HCLPFs of all corresponding non-composite fragility models, i.e., those in which β_R and β_U are kept separately (for a specific β_C , there are infinitely many possible combinations of β_R and β_U).

Seismic Robustness Analysis of Nuclear Power Plants,
Fig. 5 Example of fragility curve in logarithmic scale

The HCLPF capacity has then the following simple form:

$$HCLPF = A_m \exp(-2.33\beta_C)$$

where -2.33 is the 1 % fractile of the standard normal distribution.

The above-described relationship of the HCLPF value with the fragility curve is exemplified in Fig. 5 for an SSC with a median capacity of 0.5 g and variability parameters β_R and β_U equal to 0.3 and 0.4, respectively.

Simplified HCLPF Estimation Using the CDFM Method

The previous section described the formal definition of the HCLPF capacity based on the corresponding fragility curve. It is clear that once a full-scope fragility analysis has been performed, the HCLPF capacity can also be easily obtained.

Within SMA it is, however, not necessary to have a full description of the fragility curve; the HCLPF capacity is sufficient. As a simplified alternative to estimate the HCLPF value,

a semi-probabilistic approach has been proposed. It is referred to as “conservative deterministic failure margin” (CDFM) method; compare EPRI (1991). The CDFM method can be briefly summarized by the following four steps:

1. For the targeted HCLPF capacity (e.g., the Review Level Earthquake in an SMA), the floor responses (demand) are computed using the 84 % fractile (i.e., an 84 % probability of non-exceedance) of the ground response spectrum. Damping is to be assumed conservatively.
2. The strength parameters are evaluated at the 2 % fractile, i.e., the probability of exceedance of the selected strength is at the 98 % probability level.
3. The inelastic energy absorption factor, F_μ , should be estimated conservatively, i.e., at a 84 % probability of exceedance level.
4. If, based on the above, the following inequality is satisfied, then the targeted HCLPF capacity has been demonstrated:

$$\text{Demand/Capacity} \leq F_\mu$$

Analysis of Seismic Robustness at Plant Level

Seismic Margin Assessment (SMA)

Goals and Approaches

The main goal of an SMA is to identify the seismic capacity of the plant, i.e., the maximum level of seismic ground motion for which the plant can still be safely shut down. In addition, it is the goal of any SMA to identify the weaker components, i.e., the components limiting the seismic capacity of the plant.

There are essentially two approaches that have gained widespread acceptance and that will be described in more detail in the sequel: a success-path-based approach (“EPRI method”) and a fault-tree-based approach (“NRC method”).

Stated in simple terms, the difference of the approaches is the following:

The success-path approach identifies the components **necessary to avoid** a core damage; the plant capacity is that of the **weakest** of these components.

The fault-tree approach identifies the combinations (“minimum cutsets,” abbreviated MCS) of component failures **sufficient to cause** a core damage. For each of these MCS, the capacity is that of the strongest of these components. The plant capacity is then equal to the minimum capacity of any of the MCS capacities.

Having stated the differences between the two approaches, this introductory section deserves to be concluded by noting a fundamental, unifying feature of the two approaches, namely, that they are essentially **deterministic**. This property becomes particularly obvious when comparing the plant-level HCLPF capacity with a **target** value of the PGA. For instance the US Nuclear Regulatory Commission requires 1.67 times the PGA of the design basis earthquake; refer to NUREG (1993). In the European Utility Requirements, a minimum capacity of 1.4 times the PGA of the SSE is recommended; refer to EUR organisation (2001). The result of this comparison is a **binary and hence deterministic expression**, indicating either sufficient margin or lack thereof, but no intermediate answers.

Success-Path-Based Approach

This approach is also referred to as the EPRI (Electric Power Research Institute)-approach, because it is best described in EPRI NP-6041.

The basic concept underlying this approach is that of a success path, indicating the transition from a disturbance to the normal plant operation – caused by a design-exceeding earthquake – to a safe state, in which the fundamental safety functions (reactivity control, residual heat removal, and radioactivity confinement) are durably ensured.

An example of a success path is shown for a pressurized water reactor (PWR) in Fig. 6.

It is important to note that a reasonable success-path definition should take into account the seismic design of the plants’ safety systems. The preferred success paths should be those along which the safety functions are fulfilled by seismically designed systems.

The success-path definition should make sure that the most likely scenarios of plant disturbance after a design-exceeding seismic event are covered. At least two success paths – leading to a durable safe state of the plant – need to be defined, and one of the two success paths should include the mitigation of a small break loss of coolant accident (LOCA), unless even a small break LOCA can be excluded, e.g., due to a particularly high quality of the supports of small-bore primary piping such as measurement lines.

The above mentioned Fig. 6 describes the success path at the level of the safety functions. The goal is to ensure that all the safety functions along the success path have a sufficient margin over the SSE. This requirement obviously needs to be cascaded down to the components making up the systems fulfilling the safety functions. For example, in order to ensure steam generator (SG) feed following the earthquake, it is necessary for the emergency feedwater pump to remain operational.

The requirement of sufficient margin does not only apply to the so-called “frontline” systems, i.e., the fluid systems specifically performing the respective safety function, but also to the so-called support systems, such as electrical power supply, heating/ventilation/air-conditioning (HVAC), and instrumentation and control (I&C).

Seismic Robustness Analysis of Nuclear Power Plants, Fig. 6 Example of a success path to a safe shutdown state for a pressurized water reactor

The result of cascading the requirement for sufficient margin to the individual components consists in a list of components which are needed to fulfill the safety functions credited in the success-path definition. This list is referred to as Seismic Equipment List (SEL) or also Safe Shutdown Equipment List (SSEL).

The metric used to measure the margin is the HCLPF value introduced in earlier chapters. Since the success-path-based approach is meant to be a predominantly deterministic approach, the CDFM method is preferred.

Considering that – as a rough estimate – the size of the SEL is in the order of 10^3 components, it should become clear that it is not feasible to perform dedicated HLCLF calculations for all components of the SEL. Instead, a walkdown-based **screening process** is to be implemented. Since this screening process is common to all approaches for seismic robustness and risk assessment, it is discussed in the final chapter of this essay on practical issues.

A critical step preceding the screening process is the definition of the so-called Review Level Earthquake (RLE). It consists in a site-specific characterization of a seismic ground motion (typically a response spectrum) that is more severe than the ground motion considered in the design of the plant (i.e., the SSE).

The result of the screening process is a, typically large, set of components which are judged – based on a structured and standardized walkdown procedure – to have a generic HCLPF capacity **equal or larger** than the RLE. For the remaining components, individual HCLPF values need to be derived.

The fact that the walkdown-based screening provides only a lower bound of the **generic** HCLPF capacity, instead of a sharp value, implies that the RLE should be set high enough, so that some components for which a non-generic HCLPF is evaluated are below the RLE. Only in this way, a sharp plant HCLPF can be determined, whereas otherwise one obtains only a lower bound, because the generic HCLPFs can only be stated as being equal or higher than the RLE.

For those components for which an individual HCLPF is to be evaluated, the responses due to the RLE are needed. These may be either obtained by performing new floor response spectra and equipment response calculations based on the RLE or by scaling existing responses to the ground motion of the SSE.

Once both generic and individual HCLPF capacities have been evaluated, the overall capacity of the plant results as the lowest HCLPF of the considered equipment. This implies that both success paths must be sufficiently robust.

As a concluding remark, the deterministic nature of the success-path-based approach is emphasized, both at the individual component level (CDFM used for HCLPF estimation) and at the system modeling level (no systematic generation of minimum cutsets; see the following section).

Fault-Tree-Based Approach

This approach is also referred to as the NRC approach, because it has been proposed and developed for the NRC in NUREG (1985, 1986).

In the fault-tree-based approach, several aspects are unchanged with respect to the success-path-based approach, such as the walkdown-based screening process. The main difference compared to the success-path-based approach is that a fault-tree-based system analysis is relied upon in order to determine **minimum cutsets**, i.e., combinations of failures leading to core damage. The attribute “minimum” indicates that no individual failure event can be removed from the set without altering its property of leading to core damage. The **minimum** cutsets have

the highest risk relevance, because their probability is higher than non-minimum cutsets.

The components screened out on the basis of the walkdown observations are not included in the system modeling, i.e., only components which cannot be generically stated as having a HCLPF capacity equal or higher than the RLE are modeled in the fault trees. Individual HCLPF capacities of these components are to be estimated, either based on a fragility analysis or at least based on the CDFM method.

Performing a cutset analysis for the event trees judged as relevant for the SMA (typically at least a seismic-induced transient, such as loss of off-site power, and a small break LOCA) results in a list of minimum cutsets to be further processed as follows.

For each of the cutsets, a characteristic HCLPF capacity is obtained by taking the **maximum** HCLPF capacities of the component failure forming the cutset. From the resulting list of cutset HCLPFs, the **minimum** is then taken, in order to obtain the fault-tree-based plant HCLPF capacity. Fig. 7 is meant to illustrate the process.

Seismic Robustness Analysis of Nuclear Power Plants, Fig. 7 Min-Max operation in fault-tree-based SMA

Individual seismic-induced failure events are denoted by $SEIS_i$, $SEIS_j$, $SEIS_k$, etc.

If the fault-tree-based plant HCLPF capacity is higher than the RLE, then the plant HCLPF can only be judged as being at least equal to the RLE, since the components screened out on the basis of the walkdown observations were not included in the system modeling.

If a PSA model is available, then the effort for performing the system modeling is greatly reduced, since the seismic-induced failures of the non-screened components merely need to be added to the existing fault trees. A major benefit of reusing an existing PSA model is also the possibility to analyze mixed cutsets, i.e., combinations of seismic-induced and non-seismic-induced failures, such as random component failures or human (operator) errors.

As a final remark it is emphasized that – even though the probabilities of the cutsets are not used in the quantification of the plant HCLPF capacity – the fault-tree-based approach to SMA resembles a **probabilistic** approach, because cutsets are generated, i.e., a systematic exploration of the combinations of individual component failures is performed. Nevertheless, the subsequent steps of the procedure and – in particular – the final result are **deterministic**, since a single number (the HCLPF capacity) is used to characterize the capacity of each individual SSC.

Seismic PSA

Basic Notions

While sharing numerous aspects with SMA, seismic probabilistic safety analysis (PSA) is distinct from its deterministic counterpart (SMA) in several respects. The most prominent difference is – of course – due to the attribute “probabilistic,” which implies nondeterminacy for all the possible states of the system (i.e., the model of the NPP). Indeed, for a seismic event of a given PGA, a component may fail or may not fail, and both possibilities are assigned a **probability**. This probability is called fragility and has been introduced at length in section “[Quantification of Seismic Margin: Fragility Curves and HCLPF Values](#).” The same property of nondeterminacy

applies to the event “seismic-induced core damage,” which may or may not occur in case of a seismic event of a given PGA.

The event “seismic-induced core damage” is a central notion of both seismic PSA and SMA and hence a unifying aspect. Clearly, since both methodologies (seismic PSA and SMA) aim at analyzing the plant-level resistance to seismic events, one is – in general – not concerned with individual failures, but only with combinations of failure leading to core damage.

However, there is a significant difference: in the seismic PSA, it is assumed that the event “seismic-induced core damage” can – at least theoretically – occur due to seismic events of **any** intensity (and hence PGA).

This is where the concept of seismic hazard at the NPP site comes into the picture: it is the characterization of the seismic ground motions “to be expected” at the site (see section “[Motivation for Evaluating Seismic Robustness](#)”). For the purpose of seismic PSA, the most important characterization is afforded by the so-called hazard curve, in which the probability of observing a seismic event exceeding a PGA equal to a during a predefined time interval (typically one year) is expressed as a function of a . Thus, the hazard curve is a monotonously decreasing function $H(a)$.

In Fig. 8, a set of hazard curves is shown, each curve being associated with a probability level (50 %, 5 %, and 95 %). This characterization of the site hazard in terms of a population of hazard curves, rather than a single hazard curve, reflects the uncertainties in the hazard estimation procedures.

Recall that for each level a of the PGA, core damage may or may not occur and denote the corresponding probability by $F_A^{CDF}(a)$. The probability that a seismic event leading to core damage occurs during the time interval to which the hazard curve refers (typically one year) can be shown to be:

$$CDF = \int_{a=0}^{\infty} F_A^{CDF}(a) \frac{dH}{da} da$$

The acronym CDF denotes core damage frequency, which is – in quantitative terms – almost

Seismic Robustness Analysis of Nuclear Power Plants,

Fig. 8 Hazard curves associated with different confidence levels

identical to the annual probability of core damage.

In the practical implementation of seismic PSA, the evaluation of the CDF is however more involved. The reason is that the conditional probability of core damage $F_A^{CDF}(a)$ cannot be obtained in a closed form, because of the enormous number of component failure combinations potentially leading to core damage.

This is where the specific application, seismic PSA, becomes reminiscent of its more general “parent,” namely, level 1 PSA for internal events. In level 1 PSA risk-relevant accident progression sequences are modeled by event trees, and the potential combinations of component failures leading to unavailability of safety systems called upon during the accident progression sequences are modeled by fault trees.

These event trees and fault trees represent a (very complex) Boolean expression of the event “core damage.”

A well-established procedure for evaluating the probability of this event is to express the (complex) Boolean expression as a union of (much simpler) intersections of component failures; these intersections are called “minimum cutsets” (MCS).

For each minimum cutset, MCS_i , the contribution to the core damage frequency is

$$CDF^{(i)} = \int_{a=0}^{\infty} F_A^{(i)}(a) \frac{dH}{da} da$$

where $F_A^{(i)}(a)$ is the probability of the MCS_i , conditional on a given PGA a , and $H(a)$ is the frequency of occurrence of a seismic event with a PGA equal or higher than a .

The probability of the MCS_i is

$$F_A^{(i)}(a) = \prod_{j=1}^{n^{(i)}} f_j^{(i)}(a) \prod_{k=1}^{m^{(i)}} p_k^{(i)}$$

where $f_j^{(i)}(a)$ is the j th fragility appearing in MCS_i and $p_k^{(i)}$ is the failure probability of the k th non-seismic basic event in MCS_i . The integers $n^{(i)}$ and $m^{(i)}$ are the number of fragilities and the number of non-seismic basic events in MCS_i .

In practice the above integral is approximated by

$$CDF^{(i)} \approx \sum_{l=1}^n f\left(a_{l-\frac{1}{2}}\right)(-\Delta H_l)$$

where a_0 and a_n are the limits of the risk-relevant PGA range and the remaining a_i 's are selected at convenient points, e.g., the evaluations of the inverse hazard function at the values

10^{-1} , 10^{-2} , etc. The corresponding mid-interval fragilities $f(a_{l-\frac{1}{2}})$ are logarithmically interpolated,

$$f(a_{l-\frac{1}{2}}) = 10^{(\log_{10} f(a_{l-1}) + \log_{10} f(a_l))/2}$$

The probability of occurrence associated with each interval is $\Delta H_l = H(a_l) - H(a_{l-1})$. The total CDF is then obtained by evaluating the union of the individual MCS.

Correlation Between Seismic Failures

The issue of mutual dependence (or alternatively, correlation) between seismic-induced failures relates to the question whether the seismic-induced failure of a component, e.g., an emergency diesel generator (EDG), is more probable, under the condition that another component (e.g., the EDG of another safety train) has experienced seismic-induced failure. Several studies indicate that in seismic PSA, the effect of correlations on the seismic-induced core damage frequency (CDF) may be very significant; refer to Pellissetti and Klapp (2011) and to references 1 through 4 therein.

The most straightforward and – in general – most conservative approach consists in assuming full correlation between identical and “seismically similar” components of different, redundant safety trains, i.e., components connected by “AND”-logic. Therefore, with this model the redundancy represented by the different trains of the plant is not credited, as far as seismic-induced failures are concerned. Furthermore, for components of a single train combined under the same “OR” gate in the fault tree, the failures are assumed to be independent.

In this approach failures are thus assumed to be either fully correlated or totally uncorrelated; it is hence a binary model (black/white, zero/one) which cannot accommodate gradually varying levels of correlation. In fact, for redundant components connected by “AND”-logic, this model negates the existence of distinct failure events for the individual redundant trains and will hence also be referred to as “deterministic correlation model.” This binary, deterministic model is

conservative with respect to the probability of the top event, because correlation is detrimental (i.e., the failure probability increases) for intersection of events and beneficial for unions of events (Fig. 9).

An alternative approach, described in NUREG (1990), consists in modeling the dependencies between seismic failures in terms of the correlation coefficients between the variables characterizing the seismic demand and capacity of the SSCs. The adopted model makes full use of the possible (positive) range of correlation coefficients (between 0 and 1).

The separation of the correlation coefficients of demand and capacity reflects the difference in their respective cause: the correlation of the demand variables is due to “similarity” of the excitation experienced by distinct components (e.g., due to spatial proximity), whereas the correlation of the capacity variables is due to “similarity” in terms of the physical properties of the components (e.g., due to the fact that they have been manufactured by the same supplier). The word “similarity” is placed between quotes because it is to be understood in the statistical sense.

In this approach failure is defined in terms of the following limit-state function:

$$X = \ln\left(\frac{R}{S}\right)$$

where R and S represent the response and the strength for a given failure criterion. Failure takes place if

$$R > S \quad \Leftrightarrow \quad X > 0$$

It is convenient to model both R and S by log-normal random variables with the parameters μ_R , β_R and μ_S , β_S . According to the definition of log-normal variables, the respective companion normal variables are then $C_R = \ln R$ (with mean μ_R and standard deviation β_R) and $C_S = \ln S$ (with mean μ_S and standard deviation β_S). In view of its definition, X is then normally distributed and its mean and standard deviation are

Seismic Robustness Analysis of Nuclear Power Plants, Fig. 9 Schematic representation (Venn diagrams) of dependence between individual seismic-induced failures

$$\mu_X = \mu_R - \mu_S, \quad \beta_X = \sqrt{\beta_R^2 + \beta_S^2}$$

The probability of failure is then given by

$$P[X > 0] = 1 - \Phi\left(\frac{-\mu_X}{\beta_X}\right) = \Phi\left(\frac{\mu_X}{\beta_X}\right)$$

where Φ is the cumulative probability density function of the standard normal distribution. Considering two individual components, one may then define the random variables R_1, S_1 and R_2, S_2 , respectively, and X_1, X_2 according to the above definition of X . Assuming no cross-correlation between R_i and S_j , after some arithmetics, the correlation coefficient for X_1, X_2 may be expressed as

$$\rho_{X_1 X_2} = \frac{1}{\beta_{X_1} \beta_{X_2}} (\beta_{R_1} \beta_{R_2} \rho_{R_1 R_2} + \beta_{S_1} \beta_{S_2} \rho_{S_1 S_2})$$

$$\text{where } \beta_{X_i} = \sqrt{\beta_{R_i}^2 + \beta_{S_i}^2}.$$

It should be noted that in the above expression, the correlation coefficients $\rho_{R_1 R_2}$ and $\rho_{S_1 S_2}$ relate to

the companion normal variables of R_i and S_j , i.e., $\ln(R_i)$ and $\ln(S_j)$. The advantage of calibrating the correlation model in terms of the companion normal variables is that the meaningful range of the correlation coefficient is always $[-1, 1]$. This is not the case for log-normal random variables. It should be noted that according to its definition, the correlation coefficient $\rho_{X_1 X_2}$ depends on both the correlation coefficients and the standard deviations; this is necessary to prevent a pair of variables with a high correlation but with very small standard deviation from introducing a high overall correlation. With the above definitions, the joint probability of failure of the two components $Q_{1 \cap 2}$ is defined in terms of the following two-dimensional integral:

$$\begin{aligned} Q_{1 \cap 2} &= P[(X_1 > 0) \wedge (X_2 > 0)] \\ &= \int \int_{0 \leq x_1, x_2 \leq \infty} f_{X_1 X_2}(x_1, x_2) dx_1 dx_2 \end{aligned}$$

In the above equation, $f_{X_1 X_2}$ is the bivariate normal probability density function (PDF):

$$f_{X_1 X_2}(x_1, x_2) = \frac{1}{2\pi\beta_{X_1}\beta_{X_2}\sqrt{1-\rho_{X_1 X_2}^2}} \cdot \exp\left(-\frac{1}{2(1-\rho_{X_1 X_2}^2)}\left(\frac{(x_1-\mu_{X_1})^2}{\beta_{X_1}^2} + \frac{(x_2-\mu_{X_2})^2}{\beta_{X_2}^2} - 2\rho_{X_1 X_2}\frac{(x_1-\mu_{X_1})(x_2-\mu_{X_2})}{\beta_{X_1}\beta_{X_2}}\right)\right)$$

Accordingly, the probability of simultaneous failure of n components has the form

$$\begin{aligned} Q_{1 \cap \dots \cap n} &= P[(X_1 > 0) \wedge \dots \wedge (X_n > 0)] \\ &= \int_{0 \leq x_1, \dots, x_n \leq \infty} f_X(x) dx \end{aligned}$$

The application of the above correlation model in the context of fault-tree-based seismic PSA – using general purpose PSA software – is exemplified in Pellissetti and Klapp (2011).

Operator Actions

Earthquakes not only may impact the reliability of safety systems but also influence operator performance:

- The workload for the shift team may be higher due to a failure of operational systems.
- Spurious signals, e.g., caused by relay chatter, may make appropriate decision-making more difficult.
- Accessibility of buildings may be degraded (e.g., due to a failure of lighting or automatic locking systems) and may hence lead to smaller grace times for the necessary actions.
- Finally, earthquakes may have a direct impact on human behavior (shocks).

Past seismic PSA experiences have shown that the choice of probabilities for seismic-induced operator actions can have a significant impact on the overall PSA result. Thus, a short overview of seismic human reliability models discussed in the literature is presented in the following.

According to the **shock model**, it is conservatively assumed that all human actions fail if the peak ground acceleration exceeds a certain limit. For instance, Swiss regulations define this limit at

two times the PGA of the DBE; refer to Klügel (2007).

In the **time-dependent model** described in NUREG (1987), the seismic-induced human error probability (HEP) is expressed as a function of the time t between the earthquake and the action:

$$HEP(t) = HEP_{t=1 \text{ min}} \cdot t^{-a}$$

In the **ramp model** presented by Yokobayashi et al. (1998), the operator performance is modeled by a linear relationship between the seismic-induced HEP and the PGA until a maximum ground acceleration level L is reached.

Finally, it is worth mentioning a **model based on the CAV** (cumulative absolute velocity) value presented by Klügel (2007). No adverse effect on operator performance is expected if the CAV is below 0.16 gs. In case of stronger earthquakes,

$$HEP = HEP_{Baseline} + HEP_{GF, direct} + HEP_{Shock}$$

$HEP_{Baseline}$ is the HEP used in the PSA for internal events. $HEP_{GF, direct}$ describes structural failure of equipment (e.g., instruments, main control room boards) as well as accessibility restrictions leading to a guaranteed failure (GF) of the considered action. Finally, HEP_{Shock} models a failure of all operator actions due to operator shock, depending on the CAV: shock-induced failure is assumed with probability one if the CAV is greater than 0.16 gs and strong-motion duration exceeds a threshold value; otherwise, the probability of shock-induced failure is zero.

Uncertainty Analysis

In the earlier sections on seismic hazard analysis and – in greater detail – on fragility analysis, two sources of nondeterminism have been introduced

for the parameters relevant in a seismic PSA, i.e., the frequency of occurrence of a specific PGA (hazard) and the capacity of a component or structure (again in terms of the PGA).

These two sources of nondeterminism are random variability and (epistemic) uncertainty.

Random variability is the nondeterminism due to the inherently unpredictable nature of earthquakes and, consequently, of the earthquake-induced vibrations of the ground, the NPP civil structures, and the NPP equipment. The degree of scatter induced by random variability is termed as irreducible, since additional collection of data can improve its statistical representation, but not the scatter itself (expressed for instance by the variance or standard deviation).

Uncertainty, on the other hand, denotes the nondeterminism due to limited accuracy of models used to characterize the structural response. This lack of accuracy can be caused by inherent limitations of the model when representing the phenomena it is meant to capture (including issues such as model resolution). Also, it can be caused by limited data availability for model calibration. Another type of nondeterminism described by the term “uncertainty” is the subjective variability associated with the process of selecting a model from a set of concurrent models involving different experts. This source of uncertainty is particularly pronounced in probabilistic seismic hazard analysis.

The uncertainty in the seismic hazard is typically characterized by deriving different hazard curves for different confidence levels. In the following figure this is shown in the upper left subfigure; in this case the confidence levels are expressed by multiples of the standard deviation. For a defined value of the PGA, the uncertainty is schematically highlighted by the blue, double-sided vertical arrow.

As discussed in section “[Log-Normal Capacity Model](#),” the uncertainty associated with the seismic capacity of SSC is characterized by the uncertainty variability parameter β_U . Similarly as for the hazard curve, the uncertainty expressed by β_U can be shown graphically in terms of the fragility curves associated with the various confidence levels, as shown in the lower left

subfigure below. In this subfigure, too, for a defined value of the PGA the uncertainty in the fragility is schematically highlighted by a blue, double-sided vertical arrow.

Finally, in the right portion of the figure, it is indicated how the uncertainties in the seismic hazard and in the fragility propagate – across the convolution integral introduced previously – to the core damage frequency.

The result of this uncertainty analysis – or uncertainty propagation – is then a distribution function of the core damage frequency, as shown in the lower right subfigure. The uncertainty in the core damage frequency is here emphasized by a blue, double-sided *horizontal* arrow (Fig. 10).

Practical Issues

Seismic Equipment List

The assembly of the so-called Seismic Equipment List (SEL) is a major task in both SMA and seismic PSA. To begin with, this list includes all those systems, structures, and components (SSC) which contribute to bringing the plant to a safe shutdown state after a seismic event (this is why in EPRI (1991), this list is referred to as Safe Shutdown Equipment List (SSEL)).

For success-path-based SMA, EPRI (1991) provides detailed guidance on how to assemble the SEL. For fault-tree-based SMA and seismic PSA, it is a common situation that a PSA model already exists for the level 1 PSA of internal events. The basic events of this level 1 PSA model represent a good starting point for the SEL in this case; however, the list is to be extended by including passive components (e.g., tanks) and structures, which are typically not modeled in level 1 PSA for internal events.

Walkdown-Assisted Use of Generic Data and Screening

The number of components in the initial SEL (in the order of magnitude of 10^3) prevents a consistent degree of detail to be applied in the analysis of all of them. It is hence a common feature of SMA and seismic PSA that the initial SEL has to undergo a more or less extensive

Seismic Robustness Analysis of Nuclear Power Plants, Fig. 10 Schematic illustration of uncertainty quantification in seismic PSA

screening process in order to reduce the number of equipment items on the list. The main purpose of doing so is to enable the analysts to focus the majority of their subsequent efforts on equipment with relatively low capacity and consequently with the highest risk relevance.

The screening process takes its legitimacy from extensive earthquake experience accumulated over the years. A crucial ingredient of the process is the execution of a seismic walkdown during which it is verified, whether the equipment in the experience database is representative of the components encountered in the plant under investigation.

Summary

Seismic robustness of nuclear power plants (NPP) denotes the ability of the plant to withstand severe seismic ground motion – possibly even beyond the seismic loads against which the

plant is designed – without experiencing the degradation of equipment to a point that the plant cannot be brought and maintained in a safe shut-down state.

By necessity, seismic robustness assessment focuses on the systems, structures, and components (SSC) that are essential to the goal of a safe shutdown in the wake of an extreme seismic event. For these SSC the actual capacity – or a lower bound thereof – is evaluated; in order to ensure a common measure of this capacity for all SSC, it is quantified in terms of a characteristic ground motion parameter, typically the peak ground acceleration.

Based on the above, evaluating the seismic robustness requires both system analysis – accounting for the response of a plant to a seismic-induced accident from a process engineering point of view – and structural analysis of the essential SSC.

There are two approaches that have been found to be viable for fulfilling the above

requirements, namely, seismic margin assessment (SMA) and seismic probabilistic safety analysis (seismic PSA; in the United States, the term seismic PRA is preferred, with “risk” replacing “safety”).

The main difference between the two methods is that SMA is essentially a deterministic approach, leading to an estimate of the seismic robustness of the plant in terms of a single number, namely, the plant-level capacity.

In contrast, seismic PSA is an explicitly probabilistic approach, analyzing those combinations of component failures that prevent the plant from being transferred to a safe shutdown state, thus resulting in a damage to the reactor core. Compounding the probabilities of these combinations with the frequency of occurrence of seismic events of various intensity results in an estimate of the seismic-induced core damage frequency. A small value of the latter indicates a large seismic robustness of the plant.

Earthquakes generated by landslides and glaciers; Seismic activity of landslides and glaciers

Introduction

With few exceptions, the discovery and analysis of global earthquakes with landslides and glaciers as sources did not begin until the twenty-first century. This may come as a surprise considering that the magnitudes of such earthquakes have reached and even exceeded $M = 5$. In this essay, we describe the specific characteristics of these seismic signals and their source locations. We describe the source mechanisms and discuss the information that can be derived from interpretation of the data. In the case of landslides, the source process represents a severe hazard, and the same may be true for glaciers.

Although seismic signals from landslides and glaciers are observed at intermediate scales, we will jump from magnitudes of $M \sim 5$ to $M < 0$. The deployment of seismic stations on the target landslide or glacier is necessary to observe such weak signals. Systematic research on these microearthquakes also did not start until the twenty-first century. We offer an overview on landslide and glacier processes relevant to the generation of microearthquakes. Using selected case studies, we present the diversity of seismic signals generated by landslide and glacier sources and emphasize the close relations to geodetic and hydrometeorological data. We relate the seismic data to landslide and glacier

processes as far as possible at the current state of knowledge. The potential usage of this seismic monitoring data for hazard estimation is also addressed.

A New Class of Earthquakes

Seismic Signals from the 1980 Mount St. Helens Eruption and Landslide

Mount St. Helens (46.2°N , 122.2°W) has been the most active volcano in the Cascade Range during the Holocene. Its most impressive active phase in historical times started with a series of small earthquakes in March 1980. During the first half of the following May, seismic activity increased dramatically, and a bulge over 100 m grew outward at the mountain's north flank. The cataclysmic Plinian-style eruption, VEI 5, occurred on May 18, 1980. Within 15–20 s of a magnitude 5.1 earthquake, the volcano's bulge and summit slid away in a huge landslide (Fig. 1a). Volcanic explosions interacted with the landslide process (Fig. 1b). The landslide, comprising a volume of 2.8 km^3 , rushed first down the slope to the north and bent later to the west-northwest along the North Fork Toutle River with a speed briefly exceeding 200 km/h. The landslide covered an area of nearly 60 km^2 , with the most distal deposits traveling about 25 km (Fig. 1c). The height of Mount St. Helens was reduced from about 2950 to 2550 m (Brantley and Myers 2000).

Seismic signals from the May 18, 1980, eruption and landslide of Mount St. Helens have been recorded by seismic stations at epicentral distances from 23° up to 133° (Fig. 2a). The seismograms show strong surface waves in the period range of 100–260 s corresponding to $M_s = 5.9$. The spectra fall off very rapidly at periods shorter than 75 s. This makes these recordings significantly different from typical tectonic earthquake spectra (Fig. 2b). A cutoff period of ~ 5 s would be expected for a tectonic earthquake of similar magnitude. The low-frequency content of the Mount St. Helens recordings suggests a very slow source process. Kanamori and Given (1982) analyzed the

Seismic Sources from Landslides and Glaciers, Fig. 1 The Mount St. Helens eruption and landslide 18 May 1980; (a) the bulge at the north flank; (b) development of the landslide during eruption; (c) landslide

deposit area (Modified after Voight 1981; Moore and Albee 1981, <http://pubs.usgs.gov/gip/msh/mudflows.html>)

radiation pattern of the Love and Rayleigh waves and concluded that a subhorizontal, about southward-directed single force is an adequate source mechanism and describes the radiation pattern much better than a conventional DC. The earthquake attributed to the Mount St. Helens landslide resembled the first example of a new class of global earthquakes.

The Single-Force Seismic Source

Earthquakes of the new class produce long-period surface waves detectable on a global scale with wavelengths at least ten times the extent of the source area. The spatial migration of the source during the event cannot be resolved by long period data, therefore we consider a single force $F(t)$ varying in time but fixed in space as

Seismic Sources from Landslides and Glaciers,

Fig. 2 Recordings from seismic observatories in Japan (*MAJ*), Norway (*KON*), and Australia (*NWA*), 30 s high-cut filtered of (a) Mount St. Helens eruption and landslide, (b) Mammoth Lakes earthquake (Modified after Kanamori and Given 1982); V, R, and T are the vertical, radial and transverse components, R1 and G1 mark the first Rayleigh and Love phases

the seismic source. We refer to $\mathbf{F}(t)$ as force history. $\mathbf{F}(t)$ is the reaction force to the acceleration or deceleration $\mathbf{b}(t)$ times a mass $\mathbf{M}$ on the Earth's surface (Eq. 1).

$$\mathbf{F}(t) = -\mathbf{b}(t)\mathbf{M} \quad (1)$$

The acceleration is caused by the drop of the frictional force at a sliding plane from static equilibrium to its value during sliding. The excess gravitational forces result in the acceleration. When the slope of the landslide trajectory reduces, frictional forces exceed the driving gravitational forces, and the landslide decelerates. The momentum $\mathbf{I}(t)$ and velocity of the landslide $\mathbf{v}(t)$ follow from integration of Eq. 1 over time (Eq. 2).

$$\mathbf{I}(t) = \mathbf{v}(t)\mathbf{M} = \int_0^t \mathbf{F}(s)ds \quad (2)$$

We have $\mathbf{I}(T) = \mathbf{v}(T) = 0$, where T is the duration of the landslide. This condition imposes a constraint on the derivation of the force history $\mathbf{F}(t)$. Kanamori and Given (1982) found that the data of the Mount St. Helens eruption can be fitted by a sinusoidal $\mathbf{F}(t)$ with a period of 240 s.

CSF: Centroid Single Force

The displacement multiplied by the landslide mass at time t follows from an integration of $\mathbf{I}(t)$ (Eq. 2). The total displacement vector $\mathbf{D}$ times $\mathbf{M}$ is given by Eq. 3.

$$\mathbf{D}\mathbf{M} = \int_0^T \mathbf{I}(t)dt \quad (3)$$

The product of $\mathbf{D}$ and $\mathbf{M}$ can be derived from seismic data. Satellite images or other topographic information may also be used to break

Seismic Sources from Landslides and Glaciers,

Fig. 3 Recordings of the Alaska glacial earthquake and a M 4.2 earthquake (Modified after Ekström et al. 2003)

down the product into its factors **D** and **M**. Equations 1, 2, and 3 are valid for any surface mass accelerated or decelerated by either gravitational, inertial, or frictional forces, stress relief, or volcanic processes. Kawakatsu (1989) showed that **D M** represents the spatiotemporal centroid single force vector $\text{CSF} = -\text{D M}$, the analogue of the CMT for moment tensor seismic sources. He also provided the formalism for normal-mode inversion.

Global Glacial Earthquakes

A search for earthquakes of the new class in Arctic and Antarctic areas in data provided by global networks was carried out by Ekström et al. (2003) for the period 1999–2001 and extended to the period 1993–2008 by Tsai and Ekström (2007) and Nettles and Ekström (2010). About 243 earthquakes were found in Greenland, 14 in Antarctica, and 1 in Alaska. The one in Alaska (Fig. 3) exemplarily shows the difference

of the new-class earthquake to a nearby tectonic earthquake of similar magnitude and may explain why the new class of earthquakes has so long been undiscovered. CSF inversion was applied to the events in Greenland and Antarctica by Tsai and Ekström (2007) and Nettles and Ekström (2010), resulting in an improved location with an uncertainty of approximately 20 km. These events were clustered at or near eight fast-moving outlet glaciers with speeds >800 m/year (Fig. 4). An antisymmetric boxcar function (25 s of constant acceleration before the centroid focal time followed by 25 s of constant deceleration) was assumed in order to derive reactive forces transmitted to the Earth's crust by the displacement of a hypothetical mass. The magnitudes of centroid single force vectors were in the range $10 \cdot 10^{12} \leq \text{CSF} \leq 200 \cdot 10^{12}$ m kg, and the magnitudes were $4.6 \leq M_s \leq 5.1$. Most CSF vectors point in the opposite direction of the general flow of the glaciers.

The frequency of glacial earthquakes in Greenland is subject to seasonal variations and

Seismic Sources from Landslides and Glaciers,
Fig. 4 Glacial earthquakes in Greenland (Modified after Tsai and Ekström (2007) and Nettles and Ekström (2010))

synchronous with maximum glacier flow velocities in July–August and a corresponding minimum in January and February (Nettles et al. 2008). A power law does not properly describe the magnitude/CSF – frequency relation. It seems that each outlet glacier has its typical earthquake, which depends on glacier size, hydrological conditions, and the calving rate (Tsai and Ekström 2007).

Chen et al. (2011) detected 13 more new-class glacial earthquakes in Antarctica with epicenters at or near the Ronne Ice Shelf, Ninnis Glacier, and Vanderford Glacier (Fig. 5). At the Ronne Ice Shelf, the direction of the CSF vector was normal to the ice flow direction and parallel to the ice

front; force direction was parallel to the rift propagation direction. At Vanderford and Ninnis glaciers, CSF and local ice flow directions coincided with only one exception. The magnitudes of the glacier earthquakes in Antarctica were $4.2 \leq M_s \leq 4.9$.

Global Landslide Earthquakes

Ekström and Stark (2013) applied the detection and location method developed for the glacial earthquakes to known large landslides or areas where a potential for giant landslides can be assumed. The landslide force history $\mathbf{F}(\mathbf{t})$ was

Seismic Sources from Landslides and Glaciers,
Fig. 5 Glacial earthquakes in Antarctica (Modified after Nettles and Ekström (2010) and Chen et al. (2011))

discretized into a sequence of overlapping isosceles triangles with a half-width of 10–15 s. Momentum, displacement, and CSF were derived from $\mathbf{F}(t)$. Satellite images and other topographic information were used to separate the factors D and M out of the product CSF. Figure 6 shows, as an example, the Hunza-Attabad landslide in North Pakistan with a total mass of $140 \cdot 10^9$ kg. Ekström and Stark (2013) analyzed seismic recordings of 29 giant landslides in the Aleutian and Coast Ranges, the Rocky Mountains, the Andes, the Alpine – Himalayan orogeny, Taiwan, New Guinea, and Antarctica, with the Mount St. Helens 1980 landslide included. The magnitudes of these events range from $M_s = 4.6$ – 5.6 . The CSF can be calculated from the data provided by Ekström and Stark (2013). CSF or $\log_{10}(\text{CSF})$ significantly

correlates with the landslide mass M and the magnitude M_s (Fig. 7).

Mechanisms of Giant-Single Force Sources

Landslide: Rotating Slider Block Model

Planar slider block models have been proven to support understanding of earthquake processes considerably. When considering the application of a planar slider block to earthquake processes, the slider block is loaded by tectonic strain, and after strain release the slider block comes to rest. For landslides, the situation is different; on an inclined planar sliding plane the slider block accelerates constantly and the travel distance is not confined. A rotational slider block overcomes

Seismic Sources from Landslides and Glaciers, Fig. 6 Hunza-Attabad landslide 04 January 2010 (Modified after Ekström and Stark 2013); (a) observed and synthetic traces; (b) landslide force history; (c) source (red outline) and deposition area (blue) of the landslide;

src and dpo are centroids of the landslide mass M before and after the slide, D the trajectory derived from satellite image; given $CSF = M D = 14 \cdot 10^{13}$ kg m the landslide mass is $M \sim 14 \cdot 10^{10}$ kg; note the damming of the Hunza river

Seismic Sources from Landslides and Glaciers, Fig. 7 Relations between landslide data (Ekström and Stark 2013); (a) Mass – CSF, (b) M_s – $\log_{10}(\text{CSF})$

Seismic Sources from Landslides and Glaciers, Fig. 8 Rotational slider block model (for description of symbols see section “Landslide: Rotating Slider Block Model”)

this problem and confines the travel distance (e.g., Brückl and Parotidis 2005).

Figure 8 shows the geometry of a rotational slider block. The dynamic system of a landslide is approximated by a mathematical pendulum with the length R and the mass M concentrated to a point. The position of the mass is defined by the angle α times R . Before the landslide happens at $\alpha = \alpha_0$, the driving gravitational force $Mg \sin(-\alpha)$ is in equilibrium with the frictional force $\mu_0 Mg \cos(\alpha)$, which always acts in opposition to the direction of movement (Eq. 4). A decrease of the friction coefficient from μ_0 to μ initiates the landslide. The excess driving force is

compensated for by the inertial force $M \frac{d^2\alpha}{dt^2} R$ (Eq. 5). We only look at one half oscillation of the slider block.

$$Mg \sin(-\alpha_0) - Mg \cos(\alpha_0)\mu_0 = 0 \quad (4)$$

$$\begin{aligned} Mg \sin(-\alpha) - Mg(\cos \alpha)\mu \\ = -MR \frac{d^2\alpha}{dt^2} \end{aligned} \quad (5)$$

We consider a first-order approximation for small amplitudes ($\sin(\alpha) \sim \alpha$, $\cos(\alpha) \sim 1$) and travel distance $D \sim R(\alpha - \alpha_0)$. Introduction of these approximations and subtraction of Eq. 4 from Eq. 5 gives

$$(R/g)d^2\alpha/dt^2 + (\alpha - \alpha_0) = \mu_0 - \mu = \Delta\mu \quad (6)$$

The solution of the inhomogeneous differential equation for the initial conditions $\alpha = \alpha_0$ and $d/dt(\alpha) = 0$ is given by Eqs. 7 and 8.

$$\alpha(t) = \alpha_0 + \Delta\mu(1 - \cos(\omega_0 t)) \quad (7)$$

$$\omega_0 = 2\pi/T_0 = \sqrt{g/R} \quad (8)$$

The position angles α of the slider block at start time t_0 , stop time $t_1 = T_0/2$, and the time of maximum velocity $t_m = T_0/4$ are α_0 , $\alpha_1 = \alpha_0 + 2\Delta\mu$, and $\alpha_m = (\alpha_0 + \alpha_1)/2 = \mu = -\text{atan}(\text{CSF}_Z/\text{CSF}_h)$. The travel distance D and

maximum magnitude of the landslide force (positive for $t = t_0$, negative for $t = t_1$) are given by Eqs. 9 and 10.

$$D = \text{CSF}/M = R(\alpha_1 - \alpha_0) = 2 R \Delta\mu$$

$$= 2 \Delta\mu g (T_0/2\pi)^2 \quad (9)$$

$$F_{\max} = M g \Delta\mu = g \text{CSF}/(2R)$$

$$= \pi^2 \text{CSF} / \left(2(T_0/2)^2 \right) \quad (10)$$

The half-period $T_0/2$ of the rotational slider block is the duration of the slide or the landslide force history T . We introduce a calibration factor $k < 1$ (Eq. 11) to account for the observation of the landslide force history $F(t)$ not starting and ending with the extreme value predicted by the slider block model.

$$T_0/2 = k T \quad (11)$$

A calibration factor of $k = 0.68$ brings $F_{\max}$, calculated in Eq. 10, into a nearly perfect 1:1 relation with the $F_{\max}$ derived from the inverted force–time function (Ekström and Stark 2013; Fig. 9a). Figure 9b shows the dependence of α_m and α_0 on CSF. Over the range of CSF (approximately three decades), the average sliding angle reduces from $\sim 25^\circ$ to $\sim 10^\circ$. There is also a systematic increase of ratio $(\alpha_0 - \alpha_m)$ to α_0 with CSF from $\sim 28\%$ to $\sim 55\%$.

Calving Glacier: Toppling of an Iceberg

The large outlet glaciers of Antarctica and Greenland lose mass mainly by calving. One of the best-monitored sites where calving takes place is the front of the Jakobshavn Glacier near Ilulissat, West Greenland. On 28 May 2008, a gigantic sequence of calving events was filmed by a team of Chasing Ice (<http://earthsky.org/earth/video-largest-glacier-calving-ever-caught-on-film>). An area of the size of Manhattan calved successively over a time span of 75 min. One can observe a great number of slabs of about 1000 m in height toppling from unstable to stable equilibrium, thus pushing the iceberg mélange of

previously calved icebergs away from the ice front out to sea. This toppling of large icebergs has been considered a candidate for a seismic source of global scale (Tsai et al. 2008).

Figure 10 illustrates the geometry, kinematics, and acting forces during the toppling of an iceberg, leaving it in unstable equilibrium after calving from the front of an ice stream. The calving front may or may not be grounded. The side lengths of the cross section are H (the height before toppling) and L . The width of the iceberg is W . With $H > L$, the iceberg is initially in an unstable position. Toppling of the iceberg implies not only a rotation of $\sim 90^\circ$ but also acceleration off the glacier front. This inertial force causes a reaction force at the contact area of the iceberg with the glacier, which is then transmitted via the glacier ice to the glacier bed and represents the main part of the glacial seismic source. A first-order approximation of CSF:

$$\text{CSF} \sim M(H - L)/2, \text{ with } M$$

$$= H L W d_i \quad (12)$$

The density of ice is d_i and that of seawater d_w . The characteristic time scale of toppling can be estimated from the period of an iceberg interpreted as a mathematical pendulum:

$$T \sim 2\pi \sqrt{d_i H / ((d_w - d_i)g)} \quad (13)$$

Equations 12 and 13 do not take into consideration the remaining kinetic energy the iceberg has after reaching its stable position at the horizontal travel distance $(H - L)/2$. Furthermore, the friction between the iceberg and the glacier ice front along with the interaction of the iceberg with seawater and the mélange of smaller icebergs and fragments in front of the calving front is not taken into account. However, assuming the very reasonable dimensions $H = 800$ m, $L = 100$ m, and $W = 400$ m, $\text{CSF} \sim 10^{13}$ kg m (Eq. 12), $T \sim 150$ s (Eq. 13), and $M_s = 4.8$ according to the relation between $\log_{10}(\text{CSF})$ and M_s (Fig. 7b).

Microearthquakes Generated by Landslides

The dynamic collapse of a slope within several tens of seconds is only representative of how a landslide can end in the most extreme cases. However, the majority of landslides do not develop into dynamic and catastrophic failure but reach more or less stable final states after

phases of varying levels of activity. A deeper understanding of landslide processes and evolution is of fundamental importance for early warning and hazard estimation. Seismic activity connected to these processes can be observed by local seismic networks deployed on the landslide mass. We term microearthquakes generated by landslides LMEs (landslide microearthquakes) in the following.

Seismic Sources from Landslides and Glaciers,

Fig. 10 Toppling (capsizing) of an iceberg acting as single force seismic source; (a) kinematics and acting force (toppling may also occur by counterclockwise rotation); (b) toppling of an iceberg during the 28 May 2008 calving event at Jakobshavn glacier

Landslide Processes and Evolution

We assume brittle rheology of the rock material constituting a landslide as a precondition for seismic activity. However, under some circumstances, the landslide mass may behave as ductile, and even a brittle deformation will not necessarily act as a seismic source. In the following, we present a simplified scheme of landslide processes and possible evolutions to dynamic failure or stabilization (Fig. 11). This schema should provide a backbone for the interpretation of the seismic data provided by the case studies presented in sections “Pre- and Postfailure Processes at Steep Slopes” to “Flow”.

Slopes of a given inclination and height can only exist if the stability is guaranteed by the initial strength of the rock material. The possible

physical states are depicted in Fig. 11a in a Mohr diagram by the three Mohr's circles ($M1$, $M2$, $M3$) and Mohr-Coulomb failure criteria representing the initial and degraded strengths of the rock mass forming the slope. The Mohr's circles symbolize the states of stress, which are relevant for the stability of the slope. The initial rock strength is given by a Mohr-Coulomb failure criterion for the shear stress, with C_0 and ϕ_0 the initial cohesion and the initial friction angle. Increasing pore pressure p shifts the Mohr's circles to the left and nearer to the initial rock strength. In an extreme case of high pore pressure, a dynamic rupture could be induced; however, this is not the only situation that reduces the slope stability. Subcritical crack growth (Brückl and Parotidis 2005) supported by deep chemical

Seismic Sources from Landslides and Glaciers, Fig. 11 Landslide processes and evolution; (a) reduction of rock mass strength; (b) temporal evolution of displacement

or thermomechanical weathering (Gischig et al. 2011) may progressively damage the rock material and degrade the rock strength. Ultimately, cohesion (C_0) is completely lost and the friction angle diminished considerably from ϕ_0 to ϕ . This failure criterion of the degraded rock strength intersects Mohr's circle M1 and is tangential to M2, which means that in the first case a dynamic failure has already occurred. In the second case, the slope is in an equilibrium state of driving (gravitational) and resistive (frictional) forces. Creep of the whole slope may reduce the inclination and therefore the driving forces, and this situation is symbolized in Mohr's circle M3. It is well below the failure criterion of the degraded rock. The slope comes to an ultimate stabilization by this process.

The temporal evolution of the deformation or displacement of a landslide mass is schematically shown in Fig. 11b. The initial phase corresponds to the progressive damage from initial to degraded rock strength (Fig. 11a), where the whole rock mass of the landslide is degraded and deformed. However, deformation concentrates successively to one basal or several main sliding zones or surfaces. Toward the end of the initial phase, the further development of the slope comes to a bifurcation. In the case where Mohr's circle M1 represents the critical state of stress in the slope, the initial phase leads directly to a dynamic slope failure. In the case of Mohr's circle M2-type critical state of stress, a phase of

quasistationary creep, eventually interrupted by episodic phases of high creep or sliding velocities, follows. However, we cannot exclude that episodic high activity is the precursor for a later bifurcation between quasistationary creep and dynamic failure, as indicated in Fig. 11b by a second grey dot. The longer the quasistationary phase lasts, the more the driving forces and the radius of the Mohr's circle reduce, so that in the final state of stress represented by M3 the slope stabilizes. Decrease of the pore pressure p by improved drainage of the slope due to increased permeability of the rock mass may support stabilization.

Rockfall

Rockfall is a phenomenon occurring on slopes where, at least locally, the inclination equals or exceeds that of talus of the same rock material. It may be the consequence of weathering but also an indication of increased activity in a landslide. The seismic signature of rockfall may be a sequence of many irregular impulsive signals moving down the slope. Figure 13 shows seismic recordings from the tumbling of a medium-sized boulder (~ 2 m diameter) at the Gradenbach site (Fig. 12), images of the boulder itself and the site of heaviest impact, and the seismic location of that place (Brückl et al. 2013).

As a second example, the seismic signature of a rockfall at Steinlehen (Fig. 12) is documented in Fig. 14. This rockfall was more of a small rock

Seismic Sources from Landslides and Glaciers, Fig. 12 Monitoring sites in the European Alps

avalanche, which left behind a path resolved by ground-based InSAR monitoring. The whole event lasted around 30 s, and location applied to several time windows allowed for the tracing of the path of this rockfall. There is fair agreement between both tracing methods (Weginger 2012).

Pre- and Postfailure Processes at Steep Slopes

We denote “steep slopes” as slopes that are steeper than the initial angle of friction or the inclination of talus built up by the same rock material. The rock material of these slopes needs cohesion to balance the gravitational forces. In the case of cohesion dropping to zero because of progressive damage (Fig. 11a), the slope will immediately transit from this initial phase to dynamic failure (Fig. 11b). Identification and monitoring of precursors of this kind of dynamic rupture would be of great scientific and practical importance.

The retreat of cliffs along the British and French Channel Coasts by sea erosion-driven rockfalls is an ongoing process. Amitrano et al. (2005) report seismic monitoring of a cliff collapse at Mesnil-Val on the Normandy coast, France. Precursory seismic activity was recorded

about 1 h before the collapse. Frequency of detected seismic signals and the seismic energy obey inverse Omori’s laws. The data suggests that a warning based on increased activity could be given ~10 min before the collapse and a reliable prediction of the rupture time about 1 min in advance, provided data acquisition and continuous updating of calculations are done in real time.

The village of Randa, Matter Valley, Swiss Alps (Figs. 12, 15), was threatened by rock- and icefalls several times in its history. We anticipate a look from rock to ice and icefalls because of the similar phenomenology behind these processes in rock and ice. Icefalls were released by the Weisshorn hanging glacier five times in the last 35 years. The break-offs in 1973 and 2005 were monitored by geodetic and seismic methods. The velocity of the glacier front developed according to an inverse Omori law (Faillettaz et al. 2011) toward the instant of rupture. Log-periodic oscillations appeared superimposed on the general trend. Starting 30 days before rupture, three phases characterized by different cumulative size-frequency distribution of the signal energies and interevent waiting-time distribution behavior were identified and a correlation of seismic activity with the log-periodic oscillations established.

Seismic Sources from Landslides and Glaciers, Fig. 13 Rockfall at the Gradenbach landslide (Brückl et al. 2013); (a) main boulder; (b) recordings by the

local network; (c) main impact; (d) location by the seismic data (normalized PDF) and actual position of the impact (star)

These phases represent the development from random crack generation over crack concentration at a fracture zone to the final rupture. The findings could be the basis of an efficient in-time warning.

From the detour to ice and a hanging glacier, we revert to rock and landslides. On 18 April and 9 May 1991, two successive rockslides took place near Randa (Fig. 15). The failure volumes involved about 20 and 10 10^6 m^3 massive para- and orthogneisses (Eberhardt et al. 2004). The average slopes of the failure planes were roughly 60° and 50° (Fig. 16). The rock masses dropped down 200 and 300 m and produced M_s 4.9 and 4.8 earthquakes detected by Ekström and Stark (2013). Deformation of the slope above the actual scarp continued after the rockfall sequence of the

year 1991 with $\sim 10\text{--}20 \text{ mm/year}$ (2004–2008). A seismic monitoring campaign was started in January 2002 and continued until July 2004 (Spillmann et al. 2007), where a monitoring network was deployed above the scarp (Fig. 15). Two types of waveforms classified as LMEs were observed: 94 single events comparable to the recordings of small detonations and 129 multiple events with a more complex source time function. Frequency content of the signals reached up to 100 Hz for the surface sensors and up to 200 Hz for the borehole sensors. Most of the seismic activity was concentrated on a volume of low seismic velocities ($\leq 1500 \text{ m/s}$) near the scarp, but also deeper-reaching zones of increased seismic activity were identified, possibly outlining the scarp of a

Seismic Sources from Landslides and Glaciers, Fig. 14 Rockfall at the Steinlehn landslide (Weginger 2012); (a) differential ground based InSAR image shows the trace of a rockfall (*black arrow*); *yellow arrow* represents the path of the rockfall from the seismic data shown in (b)

future rock slide (Fig. 16). Hydrological and meteorological conditions had no impact on the seismic activity and the geodetically observed displacement rates. Most magnitudes were in the range $-2.0 < M_w < -0.5$. It is questionable if the observed seismic activity and geodetically observed displacements are postfailure relaxation processes or if they belong to the initial phase of a third, larger rock slide at Randa.

DSGSD: Deep-Seated Gravitational Slope Deformation

Deep-seated gravitational slope deformation (DSGSD) is a phenomenon frequently observed in the hard rock slopes of alpine regions. Typically, the deformation comprises the whole flank of a valley, and the maximum thickness of the deformed rock mass exceeds 100 m. The mechanisms of DSGSD are manifold, and deformation styles such as “Bergzerreiung,” “Talzuschub,” sagging or Sackung (Zischinsky 1969), and kink

band slumping (Goodman and Kieffer 2000) can be summarized under DSGSD. The initiation of DSGSD at alpine slopes mostly dates back to the retreat of the ice age glaciers, when the lateral support of the valley flank by the ice pressure was lost. This conception implies a long initial phase of mass movement, during which progressive damage degraded the rock strength almost to its residual value (see Fig. 11a; Brckl and Parotidis 2005). DSGSDs may be in a quasistationary creep phase or may exhibit episodic high deformation rates in parts of the slope or its entirety interrupting longer phases of little activity (Fig. 11b). There is currently no general answer as to whether these processes eventually lead to stabilization or a transition to dynamic rupture.

In the following, we consider the seismic signals recorded at three DSGSD examples in crystalline rocks of the European Alps: Schilienne (Helmstetter and Garambois 2010), Steinlehen (Weginger 2012), and Gradenbach (Brckl

Seismic Sources from Landslides and Glaciers,

Fig. 17 View from south to the Séchillienne DSGSD and the active zone (area colored in red); the locations of the 2 seismic micro-arrays RUI and THE are marked by symbols

et al. 2013; Mertl 2015). The locations of these landslides are shown in Fig. 12; Figs. 17, 18, and 19 supply information about the morphology, the seismic monitoring network, and partly the geology and structure of these landslides. The average slopes of these DSGSDs vary between 28° (Gradenbach) and 35° (Steinlehn).

At the Séchillienne DSGSD, a presently very active zone is located on top of the steeper lower part of the slope (marked in Fig. 17). The velocity of this active zone reached 1.4 m/year in 2008. Until April 2009, rockfalls were the most frequent seismic sources related to the dynamics recorded at the Séchillienne DSGSD. The cumulative frequency of >3000 events obeys a power law distribution over 2.5 decades of the amplitude range with an exponent corresponding to a b-value of $b = 1.1$.

Figure 20 shows typical waveforms of LMEs at the Séchillienne DSGSD. One type corresponds to impulsive sources similar to small explosions, while another event type shows mostly emergent onsets and represents source-time functions lasting ~5 s, either relatively broadband or low frequency. The LMEs cluster either in the

high-velocity area or the head scarp. It is also possible that some hypocenters are located at or near a basal shear zone. Rockfall and LME frequencies precede accelerations of the active zone by 4–5 days. Some but not all rainfall events trigger increased rockfall and seismic activity (Helmstetter and Garambois 2010).

Seismic monitoring campaigns at Steinlehn and Gradenbach had the opportunity to observe episodic phases of high landslide velocities interrupting longer periods of quasistationary creep. During June 2010, the Steinlehn DSGSD was monitored by a ground-based InSAR system installed opposite the Steinlehn DSGSD. An acceleration phase of the active slab was observed with total displacements reaching up to 0.9 m. Up to five seismic monitoring stations were operating at the Steinlehn slope during this period (Fig. 18a). Besides the rockfall (see Fig. 14), Weginger (2012) identified three classes (n, In, i in Fig. 21a) of LMEs that had their sources within the area of the accelerated slab. This classification was based on characteristic properties of the seismic signals (e.g., duration,

Seismic Sources from Landslides and Glaciers,

Fig. 18 Steinlehn DSGSD (Weginger 2012); (a) view from east to the slope with contour of the active zone; triangles mark the locations of the seismic monitoring stations, the extent of the slab accelerating during the observation period is colored in ochre; (b) geological cross section A-B (Modified after Zangerl et al. 2007)

frequency spectral characteristic, amplitude, envelopes, cross correlations, polarization). Figure 21b shows velocity and displacement of the highly active slab for the period of 10–28 June 2010. The high-velocity phase starts on 20 June and lasts until 25 June. The cumulative frequencies for LME types n, ln, and i rise from 13 June onward, and some rockfalls also occur (Fig. 21c). A sudden increase of the cumulative rockfall frequency accompanies the onset of the high-velocity phase between 20 and

21 June, and rockfall ceases completely thereafter. The cumulative frequencies of the events n, ln, i increase more or less continuously with the highest increments during the high-velocity phase. No extraordinary rainfall was reported to precede or accompany the period of high velocities of the active slab, and no external trigger of this phase is known so far. The incipient seismic and rockfall activity on 13 June was most likely the only precursor of the high-velocity phase in the following week.

Seismic Sources from Landslides and Glaciers, Fig. 19 Gradenbach DSGSD (Brückl et al. 2013): (a) Orthophoto with contour of the active zone and seismic stations GB01–GB07; the main scarp, the highly fractures zone in the uppermost area of the mass movement, and the erosional zone at the toe of the mass movement are well visible in the orthophoto; (b) cross section A-B; the depth

of the basal sliding surface or zone was determined by drilling (boreholes E2 and GB) and refraction seismic measurements (c) displacement history derived from terrestrial geodetic measurements 1969–1991, photogrammetric evaluation of the aerial photos 1962 and 1996, and GPS since 1999

The episodic high-sliding velocity phase at the Gradenbach DSGSD occurred during spring of 2009. In contrast to the Steinlehn event, the whole landslide became active due to infiltration of melting snow and precipitation (Brückl et al. 2013). Five different LME types (AA, A, B, D, tremor; Fig. 22a) besides rockfall (rf) were identified using criteria comparable to those used

for the data from the Steinlehn site (Mertl 2015). The cumulative frequencies of these events behave distinctly. Event types A and D start with the onset of snow melt (Fig. 22b–d) and high infiltration. The tremor type was only observed at that time. Thereafter, a quiet phase that lasted over 1 month followed. The beginning of the episodic phase of high creep velocity was

Seismic Sources from Landslides and Glaciers, Fig. 20 Typical waveforms and spectrograms from LMEs recorded at the Séchilienne DSGSD (Modified

after Helmstetter and Garambois 2010); (a) impulsive LME; (b) small explosion; (c) emergent and broad band LME; (d) emergent and low frequency LME

accompanied by type B microearthquakes and some rockfall. The frequency of type A and D events rose 1–2 weeks later and lasted for the rest of the episodic high-creep phase. Magnitudes of the LMEs range from -2.8 to -0.9 with a b -value of $b = 1.7$.

Though the geodetically observed movements covered the whole landslide mass, the spatial distribution of the seismic activity during the episodic high-creep phase is concentrated to limited areas (Fig. 23). Event types A, D, and tremor, which coincide with the onset of snow melt and high infiltration, are most likely very shallow events. The waveforms and coincidence in time with the onset of high creep velocities may be indications that the hypocenters of B-type LMEs are at the level of the basal sliding zone. Asperities must have been overcome before the whole

landslide mass could increase in velocity (Mertl 2015).

Flow

A flow is a spatially continuous movement in which surfaces of shear are short lived, closely spaced, and not usually preserved. Whereas in DSGSD the original structure of the rock mass is partly preserved, in a flow it is completely destroyed and mixed up. The ratio of mean thickness to length of a flow is <0.01 and significantly lower than for DSGSDs. When considering the scheme of landslide processes and evolution presented in Fig. 11a, it is evident that the initial rock (or soil) strength has been completely reduced to its residual values. Changing pore pressure may keep the flow either active or temporarily inactive (Mohr's circles M2 and

Seismic Sources from Landslides and Glaciers, Fig. 21 LMEs observed at the Steinlehn DSGSD, 10–28 June 2010 (Weginger 2012); (a) typical waveforms and spectrograms of LME types n (emerging signal, few seconds length), ln (irregular sequence of n-type signals), i

(irregular sequence of impulses over a period of several seconds); (b) displacement and velocity; (c) development of cumulative frequency of event types n, ln, i, and rf (rockfall)

M3 in Fig. 11a). Flow here represents quasistationary creep including episodic high activity, depending on infiltration and the pore pressure (Fig. 11b). The distribution of velocities in space and time within the landslide mass justifies its macroscopic description as a ductile medium. However, as the following two examples will prove, brittle deformations or interactions between pore fluid and the rock/soil mass also exist and resemble seismic sources.

The Super-Sauce landslide is a flow-type mass movement situated in the Barcelonnette basin in the southern French Alps (Fig. 12). It developed from heterogeneous soft Jurassic black marks (Fig. 24). The average slope of the flow is $\sim 23^\circ$. The landslide triggered around 1960, ruling out a causal connection to the retreat of ice age glaciers. From 1996 to 2007, the velocities covered the range of 2–30 mm/day.

Seismic monitoring at the Super-Sauce landslide was carried out between 14 and 24 July 2008 (Walter et al. 2012). Besides rockfalls, 34 LMEs were located and labeled as “slide

quakes.” They have an impulsive onset, last 2–5 s, and cover a wide frequency band (10–80 Hz). Later-arriving phases have lower frequencies (Fig. 25a). The epicenters are concentrated around the high-velocity area of the landslide. Magnitudes between $-3.2 \leq M \leq -1.3$ were detected following a power law distribution with a b-value of $b = 0.84$. The hypocenters were probably located within the uppermost few meters and not at the basal sliding zone or surface. The highest magnitudes of slide quakes followed few hours after a strong rainfall event; the temporal distribution was otherwise uniform. Single miniarrays also detected very high-frequency events (5–150 Hz) with durations of 2–20 s (Fig. 25b). These LMEs were concentrated around a stable crest within the high-velocity zone of the flow and related to fissure development in the uppermost layer of the flow. Laboratory tests proved that the flow material can have brittle rheology.

The second example of a flow is the Slumgullion landslide (Fig. 26). The landslide occurs in

Seismic Sources from Landslides and Glaciers,

Seismic Sources from Landslides and Glaciers, Fig. 24 Super-Sauce flow, *red dotted line* outlines landslide area (Walter et al. 2012)

Tertiary volcanic rocks and comprises sandy, silty clay with scattered patches of boulder debris, clay, and pond and stream sediments. The landslide consists of an active upper part,

which moved over an older, inactive lower part in its path. The average slope of the active part is 13°. The Slumgullion moves primarily by sliding along discrete bounding faults. Additionally,

Seismic Sources from Landslides and Glaciers, Fig. 25 Typical waveforms and sonograms of LMEs observed at Super-Sauce debris/mud flow (Modified after Walter et al. 2012); (a) “slide quakes”; (b) “fissure development”

differential internal processes take place at faults and fractures within the landslide body.

During 18–26 August 2009, a seismic monitoring campaign was carried out at the Slumgullion landslide (Gomberg et al. 2011). Geodetic and hydrometeorological monitoring supplemented the campaign. During the monitoring campaign, the displacement trend was ~ 10 mm/day. One stronger period of rainfall occurred during the observation period. Several seismic signals were detected and related to LMEs: “tremor” and “harmonic slide quakes” (Fig. 27a, b). The dominant energy of tremor is distributed broadly above 30–50 Hz and

diminishes toward 125 Hz. High amplitudes of tremor envelopes last < 10 s and follow irregularly in intervals of several tens of seconds. Harmonic slide quakes last ~ 2 s, their fundamental frequency is ~ 12 Hz, and no harmonics are visible throughout the whole duration. This LME type occurs more frequently during daytime, and an increase in sliding velocity is also observed during the day. Tremor and harmonic slide quakes most probably originate at the left side-bounding strike-slip faults of the landslide. The stick-slip behavior of the side-bounding strike-slip faults is explained by a transient dilatant strengthening.

Microearthquakes Generated by Glaciers

Ductile and Brittle Deformations of Glaciers

In contrast to landslides, which are intrinsic transient phenomena, glaciers or ice sheets can reach a long-lasting stationary state in steady climatic conditions. Snow is transformed to ice and added to the glacier in the accumulation area and removed in the ablation area. Glacier flow transports ice from the accumulation area to the ablation area, thereby keeping the total mass as well as the thickness of the glacier constant under stationary conditions. The glacier flow is driven by gravitational forces, controlled by the rheology of the ice and physical conditions that allow for sliding of the glacier ice over its bed (Cuffey and Paterson 2010).

We consider an infinite slab of ice with constant thickness H resting on a plane glacier bed with the slope α . Shear stress parallel to the glacier bed is proportional to $\sin(\alpha)$ and increases linearly with the overburden (Fig. 28a). According to Glen's law, the corresponding shear strain rate is proportional to the n th power of the shear stress, with $n \sim 3$.

Integration yields the velocity profile, which is an $(n + 1)$ th-order parabola. For cold glaciers, the ice temperature is below melting point at the base, and the ice may be frozen to the glacier

bed (Fig. 28b). For temperate glaciers, a thin coat of water between ice and the bedrock is assumed, and sliding occurs over the thin viscous water layer (Fig. 28c). Sliding at the glacier bed is controlled by obstacles, which are overcome either by enhanced flow due to stress concentration at the obstacles or regelation. All processes related to glacier flow described so far are either ductile (internal deformation of the ice, viscous flow of the water coat at the glacier bed, enhanced flow over obstacles) or correspond to another steady-state process (regelation) and cannot produce earthquakes.

However, the rheology of ice changes significantly in the case of the hydrostatic pressure component p of the state of stress becoming negative. In this case, the ice behaves in a brittle manner and may radiate seismic energy. First, we consider tensile crack nucleation and propagation without the influence of water. Glacier thickness adapts to varying slopes of the glacier bed by keeping the basal shear stress approximately constant. Therefore, the thickness is inversely proportional to $\sin(\alpha)$. Neglecting accumulation or ablation over a relatively short distance of an increasing slope, the velocity must increase to keep the flux of ice constant (Fig. 29). Longitudinal tensile stress must develop to extend the glacier ice moving from the gentle to the steeper slope. Surface crevasses develop

Seismic Sources from Landslides and Glaciers, Fig. 28 Planar slab of ice resting on a sloping plane; (a) shear stress parallel to surface; (b) velocity profile of a

cold glacier – no basal sliding; (c) velocity profile of a temperate glacier – basal sliding

Seismic Sources from Landslides and Glaciers, Fig. 29 Crevasse formation due to thickness adaption to increasing slope; stars mark possible locations of GMEs

to the depth at which the hydrostatic pressure equals the longitudinal tensile stress component. On alpine glaciers, surface crevasse depths seldom exceed 25–30 m. After reaching the zone of constant steeper slope, the tensile stress component disappears and the crevasses close by ductile deformation.

Water significantly influences the mechanics of landslides and glaciers. The fundamental difference between landslides and glaciers with respect to the effect of water is that buoyancy is lower than hydrostatic pressure in landslides and higher in glaciers due to the comparative densities of water ($\sim 1000 \text{ kg m}^{-3}$), rock ($\sim 2500 \text{ kg m}^{-3}$), and ice ($\sim 900 \text{ kg m}^{-3}$). Therefore, a water column of sufficient height can introduce a tensile stress regime and lead to crack development and propagation at all glacier depths. Possible scenarios are shown in Fig. 30.

Thus far, we have only considered hard-bedded glaciers where the glacier bed consists of hard rock and is not deformed by the glacier flow. However, it is well known that fast-moving outlet glaciers in Alaska, Antarctica, and Greenland rest on a basal layer of soft glacial till, which makes up a considerable part of the basal sliding

(Alley et al. 1987). The mechanical strength of glacial till obeys the Mohr-Coulomb failure criterion and may be comparable to the masses of flow-type landslides treated in section “Flow.” Although steady shear deformation may dominate, experience from seismic monitoring on landslides shows that stick-slip deformation may also occur. At the glacier beds of polythermal and temperate glaciers, there may also be asperities or “sticky spots,” which induce stick-slip basal sliding under the otherwise nonseismic deformation conditions at the glacier bed.

In the following, we term seismic activity connected to the various processes of glacier flow and observed by local networks GMEs (glacial microearthquakes).

Glacial Lake Outburst Floods at an Alpine Glacier

As an example of seismic activity of an alpine glacier, we review observations made at the polythermal Gornergletscher, Monte Rosa Massif, Switzerland (Fig. 12). At the confluence of Gornergletscher and Grenzgletscher, there is the ice-dammed Gorner lake (Fig. 31). The lake

Seismic Sources from Landslides and Glaciers, Fig. 30 Hydraulically induced fracturing in a glacier (Modified after Walter 2009; Walter et al. 2010); stars mark possible locations of GMEs; (a) opening of internal and basal crevasses due to high water pressure; meltwater

influx from active moulin or basal channels (b) closure of internal and basal crevasses due to decreasing water pressure; the collapse of a basal cavity generated during the high water pressure phase acts as seismic source

Seismic Sources from Landslides and Glaciers, Fig. 31 GMEs observed at the Gornergletscher before and during the GLOFs 2004 and 2006 (Walter 2009); (a) location of the GME clusters; fault plane strike of the

SURF A, SURF B, and INT GME clusters agree with the orientation of crevasses; dotted line outlines approximately the Gorner lake at the maximum water levels; (b) focal depths of the different GME clusters

drains during annual glacial lake outburst floods (GLOFs), which were monitored in the years 2004 and 2006 with seismic and geodetic networks (Walter 2009; Walter et al. 2010). During

the 2004 and 2006 field seasons, about 35000 and 50000 events were detected. Generally, diurnal variations in the seismicity were observed, with the peak in the early afternoon and much lower

GME activity during the nighttime and morning hours. GME clusters were recorded at three different depth levels: SURF_A and SURF_B at the depth of surface crevasses, INT at ~ 100 m depth, and BAS just above the glacier bed (Fig. 31b). The SURF_A, SURF_B, and INT GMEs have magnitudes between $-2.3 \leq M_w \leq -1.6$; the BAS GMEs reach $M_w = -0.7$. With the exception of BAS GMEs, fault planes are steeply dipping, and strike directions of the interpreted fault planes follow the general trend of surface crevasses (Fig. 31a). The radiation pattern of the SURF_A and INT LMEs can best be explained by the generation of tensile cracks, but the SURF_B events more likely result from a DC mechanism. The BAS GMEs occur on subhorizontal fault planes and are well explained by tensile cracks. The source mechanisms of the SURF_A, INT, and BAS cluster correspond to the processes schematically outlined in Figs. 29 and 30. The BAS events occurred mainly during otherwise quiescent night and early morning hours. This observation supports the idea of a collapsing basal cavity due to the reduced melt-water access and basal water pressure (Fig. 30b). The occurrence of DC-source mechanisms with the SURF_B GMEs may be due to the particular dynamic situation near the Gorner lake and the GLOF.

Arctic Glacier Prone to Surges

The temperate Bering Glacier flows from the St. Elias mountain range to its terminus on the south-central coast of Alaska and has a history of dramatic surges. Seismic monitoring was carried out between the equilibrium line altitude and the terminus (Fig. 32a) and covered the early melting period from 20 April until 19 June 2007 (West et al. 2010). Yet another surge started in 2008 (Burgess et al. 2012).

Around 160,000 events were detected during the observation period. Location of the GMEs was not attempted. The waveforms of the GMEs (Fig. 32b) show a bimodal distribution and range from high-frequency signals (20–35 Hz) to low-frequency signals (6–15 Hz). The high-frequency GMEs have impulsive source functions and were interpreted as brittle failures.

In an analogy to waveforms of volcanic earthquakes, the low-frequency tremor GMEs were explained as a fluid-driven crack model with a resonant water-filled cavity as the seismic source. Hybrid GMEs were interpreted as hydrofracturing followed by the rush of water into the new opening.

Relative maxima of the daily rate of low-frequency events precede the corresponding maxima of the high-frequency events by 1–6 days (Fig. 32c). The interpretation of this pattern is that the peaks of the low-frequency events reflect the subglacial rush in of water leading to a decoupling of the glacier from its bed and consequently enhanced flow velocities. The enhanced glacier motion is accompanied by an increase of brittle failures. Velocity data would be essential to further develop this interpretation.

Stick-slip Movement of an Antarctic Ice Stream

Bindenschadler et al. (2003) reported on major West Antarctic ice streams discharging in sudden periods of rapid motion, in particular Whillans Ice Stream (WIS) (Fig. 33a), which has an area of $200 \text{ km} \times 100 \text{ km}$ with an average ice thickness of ~ 600 m. During December 2010 and January 2011 and again during December 2011, Winberry et al. (2013) deployed a GPS and seismic network on the WIS in order to monitor the slip nucleation and the subsequent period of rapid motion (Fig. 33b). Figure 33c shows the displacements for a time span of ~ 1 h, covering the end of a preceding interevent period, the nucleation phase, the rupture, the main-slip phase, and the transition to the following interevent period. Clear evidence for the nucleation phase is shown only at one GPS station (station 1), where the rupture occurs within ~ 5 min at all stations according to the rupture propagation speed of >500 m/s. The main-slip phase lasts ~ 30 min and terminates almost simultaneously at all stations.

GMEs recorded at the individual stations correlate well in time and frequency domain with the ice stream velocities (Fig. 34). At station 1, seismicity increases at the beginning of the

Seismic Sources from Landslides and Glaciers,
Fig. 32 Seismic monitoring at the Bering glacier (Modified after West et al. 2010); (a) location of seismic

stations (red triangles); (b) waveforms; (c) temporal evolution of daily rates of high and low frequency event

nucleation phase but only begins at the other stations around the rupture time. Two different styles of GMEs or microseismicity can be distinguished. One type (Fig. 34a) is built by a sequence of fewer than a hundred to several thousand individual impulsive events. The wide distances between the seismic stations did not allow for a precise location; however, the relative timing of P and S wave arrivals and the lack of crevasses is consistent with source locations at or near the glacier bed. The individual events can be grouped into families with a high degree of similarity between each other. The same event

families persist in subsequent high-slip-rate phases. This observation is an indication of the temporal stability of subsurface asperities representing the source regions of the individual events. Other locations show in general a similar behavior but are characterized by lower frequencies, indicating larger source areas. The lack of microseismic activity or GMEs at some locations may be explained by the presence of more continuous fault gouge and higher water pressure at the glacier bed providing basal lubrication.

The second style of microseismicity is the emergent tremor (Fig. 34b). It is continuous and

Seismic Sources from Landslides and Glaciers, Fig. 33 Geodetic and seismic monitoring of an episodic high flow velocity phase at the Whillan Ice Stream (WIS); (a) location map; (b) zoom of the monitoring area with

locations of monitoring-stations; (c) displacements versus time since slip initiation; numbers and colours assign displacement data to stations in (b) (Modified after Winberry et al. 2013)

cannot be resolved into individual events. The overall spectral power of this tremor correlates well with the glacial flow velocities. Seismic energy during the tremor is concentrated in the horizontal components. A source, radiating shear energy from near the glacier bed, is consistent with this observation. The spectra reveal coherent gliding spectral lines, some of which are overtones of fundamental frequencies. Periodic stick–slip failure of small asperities could be the source mechanism of these seismic signals. Winberry et al. (2013) argue that the highly repeatable WIS system represents an excellent natural laboratory which could provide insight into friction and sliding complementary to laboratory or other field studies (e.g., Gombert et al. 2011).

Summary

A new class of global earthquakes ($M_s > 4.5$) was discovered and related to giant and catastrophic landslides or phenomena occurring near the front of fast-moving outlet glaciers in Greenland and Antarctica. The unique

characteristics of these earthquakes are the depletion of short-period energy, the elongated source time functions, and their radiation patterns, which can be explained by a single surface force better than by seismic moments. Efficient detection and location methods were developed and force histories $F(t)$ along with the centroid single force (CSF) derived. The CSF is the product of the total moving mass M and the displacement D of the centroid. It represents a major constraint on the whole source process.

Originally, the new-class global earthquakes with sources on glaciers were interpreted as stick–slip flow behavior of large portions of outlet glaciers in Greenland and Antarctica. However, the postulated movements of the ice masses could not to date be confirmed geodetically. An alternative source mechanism which generates sufficient CSF and provides the appropriate duration of the source function is the capsizing (or toppling) of large icebergs at the front of the outlet glaciers during major calving events. The basic mechanics of this process are well understood, and correlations with glacier flow, seasonal variations of iceberg production, and glacier retreat support the explanation of the

Seismic Sources from Landslides and Glaciers, Fig. 34 Waveforms observed at stations 1–4 at WIS; (a) impulsive, high frequency waveforms; (b) low frequency (Modified after Winberry et al. 2013)

majority of these earthquakes coming about through this source process.

Related to landslide-generated global earthquakes, additional information from satellite images or local reconnaissance helps to separate CSF into mass and total displacement. The inclination of the CSF vector corresponds to the Fahrböschung; the duration of the landslide force history constrains the sliding velocity. Application of a rotational slider block model allows, e.g., for estimates of the reduction of the friction coefficient from static to dynamic conditions.

Microearthquakes related to the processes in landslide masses (LMEs) that evolve in a more steady form or those in a post- or prefailure state have magnitudes of $M < 0$. Seismic networks

deployed on or very near to the landslide mass are necessary to capture these signals. A rich variety of waveforms can be observed and classified by attributes derived from the frequency content, the duration, or the shape of the envelope. Currently, no definite assignment of the different waveforms to landslide types and processes can be established. Impulsive events have been observed on slopes with steep or medium inclinations ($>20^\circ$); tremor or harmonic LMEs dominate the seismic activity of gently sloping flows. Most seismic activity on landslides is rather shallow. However, the location of a few events at the basal sliding zone cannot be excluded. Rockfall and LME frequency correlate frequently with precipitation and precede geodetically observed acceleration. An increase

in seismic activity preceding acceleration without discernible external triggers has also been observed. The general pattern of rockfall and LME activity suggests that the DSGSD- and flow-type landslides are near their yield stress not only at the basal sliding zone but also in their entire moving mass. Further progress in the understanding of LMEs would be supported by denser seismic networks including borehole seismometers as a standard. Long-term seismic monitoring covering seasonal variations and episodic high-velocity phases combined with complementary monitoring (e.g., geodetic, meteorological, hydrological, geomorphologic) are preconditions for testing refined hypotheses about LMEs and their relation to landslide processes and evolution.

Monitoring of glacier flow-related microearthquakes (GMEs) by seismic networks deployed on glaciers and supplemented by geodetic and meteorological devices provides a deeper insight into the stress distribution within the glacier ice, glacier hydraulics, and processes at the glacier bed or within a basal layer of soft sediments. The latter aspect can be exemplarily studied at the Whillans Ice Stream (WIS) in Antarctica. The ice stream exhibits a stick-slip behavior, controlled by tides with a CSF corresponding to $M_s = 5.6$. The duration of this process is above the seismically observable range, but GMEs generated by this process yield unique information about the spatial distribution and mechanical behavior of asperities or “sticky spots” in the basal layer of soft sediments. Research in this field does not only support the understanding of glacier sliding but addresses generally the friction behavior of fault gouges, e.g., the basal sliding zones of landslides or active tectonic faults.

Finally, we touch on how the potential monitoring and analyzing of landslide- and glacier-generated earthquakes contribute to prediction and early warning of catastrophic events. Global landslide or glacial earthquakes always represent the finite state of a development and may message a disaster. Prediction and early warning is not provided by the detection of these earthquakes; however, instantaneous location and

quantification by seismic methods may support mitigation measures and warnings against subsequent hazards like damming of the valley (see Fig. 6c) or increased density of icebergs. LMEs have been proven to indicate a dangerous acceleration of a landslide, usually earlier than the geodetically observable displacement. GMEs precede glacier break-off and glacial lake outburst floods (GLOFs). The results from basic research on LMEs and GMEs lead to a recommendation of seismic monitoring as an essential component of an integrated early warning system for landslides and glacial hazards.

Seismic Strengthening Strategies for Existing (Code-Deficient) Ordinary Structures

Kosmas-Athanasios Stylianidis
Civil Engineering Department, Aristotle
University of Thessaloniki, Thessaloniki, Greece

Synonyms

Intervention procedures to upgrade existing ordinary structures which are designed and executed according to older codes

Introduction

Scope of the Entry

This entry presents basic principles, criteria, and procedures in regard to the conceptual design of seismic strengthening of existing ordinary structures and its treatment in current codes. In this context, certain code provisions constitute a significant part of the present entry.

Although it can be read by nonexperts, this entry is mainly addressed to structural engineers involved in the design of structures and interventions in buildings.

Notes on Terminology Used

The terms used in the entry are standard and familiar to engineers; nevertheless some clarifications are in order:

Seismic: The entry is restricted to seismic upgrading only. Certain aspects of the methodology may also apply to upgrading against other actions. However, it is pointed out that the main characteristic of a seismic strengthening strategy is the fact that an earthquake is an accidental load. In this sense, it is possible to define target performance levels, dependent on the level of the design earthquake, which in general can be related to the accepted risk. This probability leads to a compromise between “desirable” and “feasible,” i.e.,

instead of a practically unfeasible (due to cost or disturbance of use) high target, the adoption of a lower, yet feasible, target is more pragmatic. This option is typically not available in the case of upgrading against permanent loads.

Intervention: The term structural intervention implies any operation that results in the desired modification of existing mechanical characteristics of a member or a structure and has as a consequence the modification of its response.

Repair: The term implies the process of intervention to a structure damaged by any cause that reinstates the mechanical characteristics of its structural members to their pre-damage level and restores its original structural capacity.

Strengthening: The term implies the process of intervention to a structure with or without damage, which increases the capacity and/or ductility of a member or the entire structure to a level higher than that prescribed in the original design.

Strategy: It is a high-level plan to achieve certain objectives, usually under uncertain conditions.

Technique: It is a procedure to be implemented to complete a task (see also Wikipedia 2014).

Code Deficient: The term refers to buildings designed according to older seismic codes or without any code. It is typically the case that contemporary codes introduce significantly higher demands than older codes and this is the main reason that upgrading is needed.

Ordinary Structures: This term includes mostly above surface R/C building structures. Underground, special structures (bridges, chimneys, etc.) and historical buildings fall beyond the scope of this entry. The same principles can be applied to structures made of different structural materials, such as steel, masonry, and wood, after suitable adaptation.

Sources

The entry is primarily based on two sources, the European Standard EN 1998–3 (2005) and the Greek Code of Structural Interventions (2012), which standardize the existing knowledge on upgrading of ordinary structures.

Assessment

General

The assessment of an existing structure is not strictly mandatory, but it is valuable, since it reveals the weaknesses of the structural system and indicates the strengthening measures to be taken. In this sense, the assessment is integrated in the design strategy and is strongly recommended.

The assessment of existing structures follows the steps below:

- Collection of data (investigation of structural history)
- Analysis (see Section [Methods of Analysis for Assessment and Redesign](#) of the present entry)
- Verification against limit states (see [Section Compliance Criteria for Assessment and Redesign](#) of the present entry)

Scope

- (a) The purpose of the assessment of an existing structure is the evaluation of its available bearing capacity and the verification that the minimum mandatory requirements imposed by the existing codes are met.
- (b) To estimate the available bearing capacity of the structure, the data from the structural history survey should be taken into account (see Greek Code of Structural Interventions (2012), Chap. 3, and European Standard EN 1998-3 (2005), Chap. 3).
- (c) The designer should prescribe and supervise a series of investigating works in order to document and justify the assumptions on which the assessment will be based.
- (d) The process of assessment differs depending on the existence or otherwise of damage in the building assessed.
- (e) In case of no damage, the result of the assessment, depending on the selected redesign objective, will dictate the decision for potential retrofit.
- (f) In the presence of damage, due to any past actions (prescribed or not by the standards applicable up to then), the assessment process includes two phases:
 - (i) First, the structure is assessed as it is, taking damage into account. Depending on

the selected redesign objective, the result of the assessment might lead to a decision for intervention (repair and/or retrofit).

- (ii) In case that intervention is required, the structure is assessed at its pristine condition, i.e., assuming that damage will be repaired. Depending on the selected redesign objective, the result of this assessment will lead to the decision for repair only or for repair and retrofit.

Collection of Data

The collection of the data required for the assessment should be governed by the following principles:

- (a) The data required for the assessment of the bearing capacity of existing structures should be cross-verified and properly calibrated, wherever possible.
- (b) It is recommended that the program of field and laboratory investigations be designed, executed, and supervised by the designer of the assessment, according to the specific design requirements.
- (c) The reliability of the data collected should be properly taken into account in the assessment of the existing structure and the development of the intervention strategy.

Data Reliability Level (DRL)

General

- (a) The reliability level of data (DRL) related to actions or resistances indicates the adequacy of the information regarding the existing building and is taken into account in the assessment and redesign. In existing structures, the numerical values of the data required for the assessment and redesign are usually characterized by a higher uncertainty than in the case of new structures.
- (b) DRL is not necessarily the same for the entire building. Individual DRLs for the various subcategories of information can be determined. For the selection of methods of analysis, the most unfavorable among the individual DRLs are used.

- (c) The concept of DRL is also applied in assessing the completeness of the survey of the structure and infill walls, especially in case of hidden elements. The effects of uncertainties can be taken into account in actions or resistances depending on the case (e.g., uncertainty in the thickness of the flooring of the slab will be taken into account in actions; uncertainty in the thickness of the slab itself will be considered mainly in the resistances).

Description of DRLs

- (a) According to the European Standard EN 1998-3 (2005), three knowledge levels of data are adopted: (KL) 1–3 (limited, normal, full). According to the Greek Code of Structural Interventions (2012), Chap. 3, these levels correspond to high, satisfactory, and tolerable data reliability level.
- (b) Regarding the self-weight, the characteristic value considered must be the most unfavorable value that is consistent with the geometry of the structure and/or applies for such structures.
- (c) Regarding the resistances, their values can be determined from the dimensions, reinforcement, and material characteristics that lead to the justification of prior behavior of the structure. So, for example, a strength value that corresponds to the ultimate resistance of a cross section under the existing acting loads can be used. Similarly, dimensions of inaccessible foundations can be estimated with the assumption that they correspond to the ultimate soil bearing capacity under acting loads, etc.

Impact of DRL on the Assessment and Redesign Depending on the reliability of the data:

- (a) The appropriate safety factors γ_f for certain actions with uncertain values are selected (see Greek Code of Structural Interventions 2012, Chap. 4). Such may be the case for the representative values of some indirect actions (e.g., soil pressure) and the weight of inaccessible infill walls or coating/plastering.

In certain cases of high uncertainty (and if it is considered that the influence of the magnitude of the corresponding action is significant), consideration of two “reasonably extreme” representative values ($S_{k, \min}$ and $S_{k, \max}$) is recommended.

- (b) The appropriate safety factors γ_m are selected according to the data for existing materials (see also Greek Code of Structural Interventions 2012, Chap. 4). Material data are the dimensions of members and strengths of concrete and reinforcing steel, as well as the actual reinforcement detailing, anchoring, starter bars etc. that determine the resistances.

Assessment Principles

General

Assessment of existing structures follows the principles listed below:

- (a) When the existing structural system is expected to contribute to the redesigned structural system solely by resisting vertical loads, its assessment may be performed based on simple, yet conservative, methods.

In this case, the accuracy of the assessment method used should be adjusted to the desired goal. For instance, an approximate, yet conservative, assessment method is sufficient to demonstrate the adequacy of the existing structural system against vertical loads. When the existing structural system is apparently inadequate and is expected to be fully demolished, its assessment is not necessary.

- (b) However, when the existing structural system is expected to contribute to the redesigned structural system by resisting both vertical and seismic loads, it should be assessed based on the principles below. For the assessment of the structure against vertical loads, it is possible to use the methods prescribed by Eurocode 2 (EN 1992-1-1 2004), appropriately adapted:

- (i) The assessment is made using analytical methods (see Section [Methods of Analysis for Assessment and Redesign](#)

of the present entry). Especially in the case of structures without damage, for which the approved design study (which has been applied) is available, the assessment could be based on it.

- (ii) The numerical models to be used for the assessment may represent the entire structure or individual members. Different numerical models may be used, depending on the type of the imposed actions. In general, the types of numerical models should be selected consistently with the calculation methods to be applied. Advanced methods of analysis should be combined with detailed numerical models.
- (iii) It is recommended that the accuracy of the methods used be compatible with the accuracy of the data. High-quality numerical analysis is reliable only if it is based on equally reliable data.
- (iv) The use of empirical–analytical or purely empirical methods is allowed only in cases covered by relevant special provisions issued by the competent public authority. Such specific provisions can be issued, provided that they refer to a building stock with common, known, features and that they are always preceded by a proper investigation.
- (v) In cases of structures that have already suffered damage or deterioration, the applied assessment method must be able to interpret, as a rough approximation, both the type and the location of this significant damage. In structures of high importance, where damage has been identified, parametric analyses may be required to achieve the interpretation of damage based on their type and location.

The possible interpretation of damage, in terms of type and location, constitutes an acceptance criterion for the analytical methods used. Possible parameters may include non-visible geometrical data, mechanical characteristics that have not been investigated, random

combinations of actions assumed to have been applied in the past, etc.

- (vi) For analysis, limit state control, verification of the adopted behavior factor, control of the imposed displacements, and local ductility indices, Sections [Methods of Analysis for Assessment and Redesign](#) and [Compliance Criteria for Assessment and Redesign](#) of the present entry are applied. In the case of masonry walls, paragraph [Consideration of Masonry Infill Walls](#) is applied.
- (vii) In many cases, a quick assessment of the loss of bearing capacity of a damaged or deteriorated structure may be useful and/or necessary. This estimate can be made based on the intensity and extent of damage, as derived according to well-established (refined or approximate) methods.

Consideration of Masonry Infill Walls

- (a) It is not permitted to consider masonry infill walls as part of the system that carries non-seismic actions (such as gravity loads). To calculate the internal forces of the structure due to non-seismic actions, numerical models are used that do not include masonry infill walls or do not impose stresses (induced by vertical loads) to them.
- (b) It is recommended to consider masonry infill walls as part of the seismic action resisting system.
- (c) It is mandatory to consider masonry infill walls as part of the system resisting seismic actions, when this decision has an adverse effect on the results obtained for the structural system at a global or local level.

The assessment of whether the influence of infill walls is favorable or unfavorable has to be made by the designer; however, the difficulty of the assessment has to be noted, particularly in the case that analysis data and calculations are not available. As a result, the above assessment will be on the safety side, if the masonry infills are introduced in advance to the numerical analysis models.

Redesign

General

The redesign of existing structures follows these steps:

- Conceptual and preliminary design
- Analysis (see Section [Methods of Analysis for Assessment and Redesign](#) of the present entry)
- Verification against limit states (see Section [Compliance Criteria for Assessment and Redesign](#) of the present entry)

Conceptual and Preliminary Design

- (a) According to the criteria and the types of structural interventions, to be presented in Section [Selection Criteria and Types of Structural Interventions](#), an intervention strategy is devised and the type and extent of interventions is decided.

Decisions on the appropriate strategy and the subsequent type of interventions for each case should be made on the basis of all information obtained during the assessment stage of the existing structure. The perception of the overall behavior of the building and the identification of its weaknesses, such as inadequate strength or stiffness or ductility, the unfavorable structural system, individual weaknesses, etc., should be dominant in the decision-making process.

Regardless of the analysis method that will be eventually adopted for the redesigned structure, inelastic static analysis may provide substantial assistance in identifying these weaknesses. Furthermore, with the aid of the above method, it is feasible to preliminarily select the characteristics of the types of intervention that will be prioritized.

- (b) In all cases this selection should be justified (compared with other possible options), while the anticipated post-intervention behavior of the building should also be described qualitatively.
- (c) A preliminary estimate of the dimensions and strength of the materials used and the modified stiffness of the structural elements undergoing intervention should be made.

- (d) Preliminary estimate is made of the ductility class that the structure will fall into after the intervention, or (in case of application of inelastic static analysis) preliminary estimate is made of either the amplitude of the target displacement or the tolerable rotation angle of all structural members after intervention.

Assessment and Redesign Objectives

General

- (a) In order to satisfy broader socioeconomic needs, various “performance levels” (target behaviors) are stipulated under relevant prescribed design earthquakes.
- (b) The objectives of the assessment or redesign (Table 1; see Greek Code of Structural Interventions 2012, Chap. 2.2) are combinations of both a performance level and a seismic action, given an “acceptable probability of exceedance within the technical life cycle of the building” (design earthquake). The European Standard EN 1998–3 (2005) specifies that these levels should be defined in the National Annex (for each country).
- (c) In the present entry, objectives that refer solely to the structural system are prescribed. In contrast, no objectives are set for the nonstructural system.

The relevant fundamental requirements, set by Chap. 2.1 of European Standard EN 1998–3 (2005), are satisfied through Table 1. In the case of two reassessment objectives, the possible pairs are B1 and A2 or C1 and B2.

The term “structural system” is used here in the classical sense and corresponds to the system bearing vertical loads. Accordingly, the term “nonstructural system” corresponds to the system that does not participate in bearing vertical loads. It is noted that the above conditions are not associated with the terms “primary” and “secondary” structural elements that are used in subsequent paragraphs.

- (d) The objectives of the assessment or redesign are not necessarily identical. The objectives of redesign may be higher than those of the assessment.

Seismic Strengthening Strategies for Existing (Code-Deficient) Ordinary Structures, Table 1 Assessment or redesign objectives of the structure

Probability of exceedance of seismic action within a conventional life cycle of 50 years (%)	Performance level		
	Damage limitation (DL)	Significant damage (SD)	Near collapse (NC)
10	A1	1	C1
50	A2	2	C2

- (e) The minimum acceptable assessment or redesign objectives for the structural system of existing buildings are defined ad hoc by the public authority. In special cases, the public authority may designate additional objectives for assessment or redesign of the nonbearing system as well. In this case, the same authority also defines the criteria for meeting the respective objectives.
- (f) In any case, the reassessment objective (assessment or redesign) is chosen by the project owner, provided that it is equal to or higher than the above minimum acceptable objectives. In defining these objectives, the following criteria (among others) should be taken into account:
- Importance of the building (e.g., temporary structure, ordinary residential house, area of public gathering, area of crisis management, high-risk facility)
 - Available financial resources during the given period
- (g) The owner of the project or the public authority has to define the time frame within which the relevant interventions will be conducted, wherever required.
- (h) A nominal life cycle equal to the conventional lifetime of 50 years is generally accepted, regardless of the estimated “actual” remaining life of the building. An exception to this rule is permitted only under special circumstances where the remaining lifetime is fully guaranteed, based on the judgment and approval of the public authority; in such a case, the seismic actions are modified accordingly.

It is noted that according to Table 1, design objective B1 is the objective normally set for new structures.

The adoption of an assessment or redesign objective associated with a probability of exceedance of the seismic action of 50 % will generally lead to more frequent, more extensive, and more severe damage compared to a corresponding objective associated with a probability of exceedance of seismic action equal to 10 %.

The probability of exceedance of 50 % (maximum tolerable) in 50 years corresponds to an average return period of about 70 years, while a probability of exceedance of 10 % in 50 years corresponds to an average return period of approximately 475 years.

Structural Performance Levels

The performance levels of the structure are defined as follows [see also Chap. 2.1 of European Standard EN 1998–3 (2005)]:

- (a) “Damage Limitation” (A) is a condition wherein the structure is only lightly damaged, with reinforced concrete elements prevented from significant yielding and retaining their strength and stiffness properties. Nonstructural components, such as partitions and infills, may show distributed cracking, but the damage could be economically repaired. Permanent drifts are negligible. The structure does not need any repair measures. No building operation is interrupted during and after the design earthquake, with the possible exception of minor importance functions. A few hairline cracks may occur in the structure.
- (b) “Significant Damage” (B) is a condition wherein the structure is significantly damaged, with some residual lateral strength and stiffness, and vertical elements are capable of sustaining vertical loads. Nonstructural components are damaged, although partitions and infills have not failed out of plane. Moderate permanent drifts are present. The structure can sustain aftershocks of moderate intensity. The damage to the structure, expected to occur during the design earthquake, is

repairable but possibly uneconomic, without causing loss or serious injury of people.

- (c) “Near Collapse” (C) is a condition wherein the structure is heavily damaged, with low residual lateral strength and stiffness, although vertical elements are still capable of sustaining vertical loads. Most nonstructural components have collapsed. Large permanent drifts are present. The structure is near collapse and would probably not survive another earthquake, even of moderate intensity. The damage to the structure is in general unrepairable. Injuries of certain individuals due to structural damage or falling elements of the nonbearing structure or other objects are not excluded.

The term “unrepairable damage” refers to serious or severe damage, for which strengthening (and not just repair) or replacement or substitution of the component or the entire structure is required.

General Principles for Pre- and Post-earthquake Intervention Decisions

Selection Criteria and Types of Structural Interventions

- (a) Based on the conclusions drawn during the assessment of the structure, and the nature, extent, and intensity of the damage or deterioration (if any), intervention-related decisions are made, aiming to (a) meet the basic requirements of the seismic code, (b) minimize the cost, and (c) serve the needs of the society.
- (b) The selection of the type of structural intervention should be made primarily on the basis of general cost- and time-related criteria, the availability of the resources required, architectural or other needs, etc. In this selection, the financial (or other) value of the structure should also be taken into consideration, both prior and subsequent to the intervention.

Such general criteria include the following:

- The cost, both initial and long term (i.e., the cost of maintenance and possible future damage or deterioration), compared

to the importance and age of the building under consideration.

- The available quality of the work (it is very important that intervention measures be compatible with available resources and available quality of work).
 - The availability of an adequate quality control system.
 - The use of the building (possible consequences of the intervention works to the use of the building).
 - The design, from an aesthetic point of view (the intervention scheme may vary between a fully invisible intervention and a deliberately distinctive set of new or added members).
 - The conservation of the architectural identity and integrity of historical buildings and the consideration of the degree of reversibility of the interventions.
 - The duration of works.
- (c) The selection of the type, technique, scale, and timing of the intervention should be based on technical criteria related to the observed current state of the building, as well as to a provision to maximize the ability of the structure to absorb seismic energy (ductility) after the intervention.

Such technical criteria include the following:

- All identified serious deficiencies must be remedied.
- All identified serious damage (and deterioration) in primary structural members must be repaired properly.
- In the case of highly irregular buildings (mainly in terms of distribution of their overstrength, both in plan and in height of the building), structural regularity should be improved to the maximum possible extent.
- All resistance requirements in critical regions of primary structural members (i.e., the required resistance and plastic deformation capacity) must be satisfied after the intervention (distinguishing between primary and secondary members).
- Where possible, the increase of local ductility in critical regions should be pursued.

Particular provision should be taken, to the largest extent possible, so that the local repair and strengthening do not diversely affect the available ductility within the critical region.

- In special cases, the durability of both new and original structural members and the potential acceleration of the deterioration should be taken into consideration.

Types of Intervention and Their Consequences

- (a) Based on the foregoing criteria and the results of the assessment of the structure, appropriate types of intervention should be ad hoc selected for individual structural members or the entire building and the nonstructural system (if required), always taking into account the side effect of the interventions on the foundations. This selection is part of an intervention strategy, which aims to improve the seismic behavior of the building by modifying or controlling the basic parameters that affect its seismic behavior. In order to achieve a reduction of seismic risk, strategies of technical or managerial nature, or combination of the two, can be adopted.

A number of technical and managerial strategies are indicatively given herein:

Technical strategies:

- Enhancement of the building strength
- Enhancement of the building stiffness
- Enhancement of the deformation capacity of the structural members
- Reduction of seismic demand

Managerial strategies:

- Limitation or change of use of the building.
- Partial or global demolition (i.e., of a number of storeys).
- “Rigid body” transfer of the entire structure to another location.
- Decision for “no intervention”. In such a case, a reduction of the nominal life cycle of the structure can be accepted, under the condition that upon expiry of this period, demolition of the structure is guaranteed.

Some types of interventions in structural elements associated with specific strengthening strategies of technical nature are listed below:

- The enhancement of strength and stiffness is alternatively achieved by selective or large-scale strengthening of structural members or by the addition of new elements that can resist either partially or fully the seismic actions (e.g., reinforced concrete shear walls, steel trusses, infill walls, etc.). In this case, particular attention should be given to the design of the foundation due to the increase of both the structural mass and the seismic loads.
- The enhancement of post-elastic deformation capacity (ductility) is achieved by improving the confinement of existing members, e.g., with external connectors, strips of steel or fiber-reinforced polymers, etc.
- The remedy of critical deficiencies refers to alleviating those features that lead to unfavorable seismic behavior. Indicatively:
 - Modification of the structural system (abolition of certain expansion joints, replacement of sensitive members, alteration actions aiming at a more regular and ductile system)
 - Addition of special links to connect the brittle masonry and surrounding member, whenever this is permitted by the strength of masonry
 - Local or global modification of members with or without damage
 - Full replacement of inadequate members or members that have suffered extensive damage
 - Redistribution of demand (e.g., through external prestressing)
- The reduction of seismic demand is achieved by reducing the mass of the structure and modifying the structural system toward a favorable shift of the fundamental period of the structure [e.g., through seismic isolation systems or absorption of seismic energy; see

Chap. 10 of European Standard EN 1998–1 (2004)].

- (b) In cases where, for the redesign objective set, the seismic behavior of nonbearing structural members might endanger the lives of the occupants (or third persons) or might have consequences to stored goods, measures should be taken to repair or strengthen the particular members.

In such cases, local or global collapse should be prevented by:

- Appropriate links to the structural members or by taking supportive measures to prevent possible fallout of parts of those members
 - The improvement of the mechanical characteristics of nonstructural members
- (c) The potential impact of repairs and strengthening of nonstructural members should be taken into account.
 - (d) The side effects of all structural interventions on the local and global capacity of the building to absorb seismic energy should be taken into account.

The enhancement of strength usually leads to a reduction in ductility, unless special measures are taken (e.g., in reinforced concrete elements, the increase of the tensile reinforcement should be in principle accompanied by a sufficient increase of the compression reinforcement and of confinement).

Methods of Analysis for Assessment and Redesign

General

- (a) The action effects and/or the required plastic rotations of all structural members of the building under the design earthquake and other combinations of actions are derived using appropriate analysis methods.

To determine the internal forces and displacements, it is permissible to ignore proximity to other buildings.

- (b) The selection of the appropriate method of analysis should be based on the importance of the building and its potential damage or

deterioration, as well as on the available data regarding the cross sections and strength of its structural members.

Whenever possible, it is recommended to calibrate such methods through comparison with the behavior of buildings that have already been studied with the particular methods.

- (c) Where appropriate, additional partial factors γ_{sd} will be applied to account for the uncertainties related to the numerical analysis models.

Consideration of Masonry Infill Walls

Consideration of the masonry infill walls in the redesigned structure can be carried out, subject to the conditions of paragraph Consideration of Masonry Infill Walls

As part of the redesign process, it is desirable to make every effort to mitigate the potential deficiencies imposed by the masonry infills. Addition or upgrading of masonry infills can be used for the improvement and strengthening of existing buildings, subject to conditions of paragraph Consideration of Masonry Infill Walls

Methods of Analysis

For the assessment and redesign of a building, one of the following analysis methods may be used. The field of application of each analysis method depends on satisfying a number of conditions, primarily related to regularity (see Greek Code of Structural Interventions 2012, Chap. 5):

- (a) Elastic (equivalent) static analysis with global (q) or local (m) behavior (or ductility) factors, regardless of the data reliability level.
- (b) Elastic dynamic analysis with global (q) or local (m) behavior (or ductility) factors, regardless of the data reliability level.
- (c) Inelastic static analysis. In this case, it is recommended to ensure, as a minimum, a “satisfactory” data reliability level.
- (d) Inelastic dynamic (response history) analysis. In this case, it is again recommended to ensure, as a minimum, a “satisfactory” data reliability level.

- (e) In special cases, solely for the assessment of existing buildings, it is permitted to estimate the demand approximately, without detailed analysis involving a finite element model of the entire building.
- (f) Apart from the above analytical methods, solely for the assessment of existing buildings, in special cases and for specific objectives, it is possible to use empirical methods.
- (g) It is permitted to apply the elastic methods provided that all the following conditions apply:

- (i) The failure index (λ) of each primary member is in general lower than 2.5.

The adopted threshold value of the failure index (λ) generally implies that the available strength of each primary structural member is at least 40 % of the demand resulting from an elastic seismic analysis without reducing the seismic action, i.e., for $q = 1$.

- (ii) The average failure index ($\bar{\lambda}_k$) in each storey does not exceed 1.50 times the average failure index of the storey above or below.

It is deemed that the average failure index ($\bar{\lambda}_k$) identifies the regularity in the resistance (strength) along the building height, whereas its adopted threshold value ensures that no weak, in flexure and/or shear, intermediate storey exists.

- (iii) The failure index (λ) of each primary structural member that is located on one side of the building, for a given direction of seismic action, does not exceed 1.50 times the average failure index (λ) of a primary member that is located on any other side of the same storey.

It is deemed that with this provision, issues of torsionally sensitive storeys are addressed.

Principal (or Primary) and Secondary Structural Members

The individual parts of the structure of a building and the individual structural elements (members) affecting the stiffness and demand distribution within the building, or the members that are

loaded due to lateral displacements of the building, can be distinguished during assessment or redesign into “principal” (or “primary”) and “secondary.”

In general, the structural members or substructures that contribute to the strength and stability of a building under seismic loading will be characterized as principal. The remaining structural elements or substructures will be characterized as secondary. See also related Chap. 4.2.2 of European Standard EN 1998–1 (2004).

The main consequence of classifying a structural member (or substructure) as a secondary is that for these members, different performance criteria apply, i.e., they are permitted to undergo larger displacements and suffer higher damage compared to the primary elements.

In cases where damage limitation after the earthquake has been set as the assessment or redesign objective, the above distinction between primary and secondary data is not permitted.

For the masonry infill walls, which do not carry vertical loads (see paragraph Consideration of Masonry Infill Walls), the distinction between primary and secondary members does not apply. Where those members are considered as part of the seismic action resisting system, they are addressed and verified separately.

Compliance Criteria for Assessment and Redesign

General

- (a) Compliance with the selected performance level for assessment and redesign is achieved by adoption of the seismic action, method of analysis, verification, and detailing procedures, appropriate for the different structural materials (concrete, steel, masonry) within the scope of the code used.
- (b) Except when using the q-factor approach, compliance is checked by making use of the seismic action as defined in Table 1.
- (c) For the verification of structural elements, a distinction is made between “ductile” and “brittle” ones. Except when using the q-factor approach, the former is verified by checking

that demands do not exceed the corresponding capacities in terms of deformations. The latter is verified by checking that demands do not exceed the corresponding capacities in terms of strengths (see Greek Code of Structural Interventions (2012), Chap. 9).

- (d) Alternatively, a q -factor approach may be used, where use is made of a seismic action (response spectrum) reduced by a q -factor. In safety verifications all structural elements are verified by checking that demands due to the reduced seismic action do not exceed the corresponding capacities in terms of strength.
- (e) For the estimation of the capacities of ductile or brittle elements, where these will be compared with demands for safety verifications, mean value properties of the existing materials are used as directly obtained from in situ tests and from additional sources of information. Nominal properties are used for new or added materials.
- (f) Some of the existing structural elements can be designated as “secondary seismic” (see Chapter Principal (or Primary) and Secondary Structural Members), in accordance with the definitions in European Standard EN 1998–1 (2004), Chap. 4.2.2 (1)P, (2) and (3). “Secondary seismic” elements have to be verified according to the same compliance criteria as primary seismic ones, but using less conservative estimates of their capacity than for elements considered as “primary seismic.”
- (b) The partial safety factors of the existing and added materials should take into account the geometrical uncertainties, the dispersion of material properties, the relevant information available on site, as well as any uncertainties due to the nature of works and the difficulties of effective quality control (see Greek Code of Structural Interventions 2012, Chaps. 4, 7–9).
- (c) Where appropriate, additional factors γ_{Rd} are applied to account for the uncertainties arising from the numerical modeling of the resistance in critical (or noncritical) regions.
- (d) In cases of structural interventions against seismic actions, the damage limitation verification is made in accordance with appropriate provisions (see Greek Code of Structural Interventions 2012, Chap. 9). The damage limitation verification generally includes the primary and secondary structural members, infills, and appendages.

Safety Verifications

- (a) The available resistance in the critical regions of all structural members (i.e., the resistance quantities and/or the tolerable plastic rotations) should be calculated on the basis of rational numerical models, which are widely accepted by the international scientific community, especially in terms of force transfer between existing and added materials or members (see Greek Code of Structural Interventions (2012), Chap. 6 for the numerical models, Chap. 7 for the determination of the behavior of structural members, and Chap. 8 for the design of the interventions).
- (b) The local available ductility in critical regions
- (c) The available secondary resistance mechanisms at large relative displacements
- (d) The potential consequences of the brittleness of a limited number of structural members on the ductility of the entire structure

Verification of the Adopted Behavior Factor

After the verifications above, it is required to approximately reevaluate the predefined behavior factor for the repaired–strengthened building, taking into account all the criteria favoring energy absorption, such as:

- (a) The sequence of failure of horizontal and vertical structural members
- (b) The type of failure in critical regions of each structural member (i.e., the ratio of the ultimate shear force to the effective shear at the time of flexural failure, as imposed by capacity design)
- (c) The local available ductility in critical regions
- (d) The available secondary resistance mechanisms at large relative displacements
- (e) The potential consequences of the brittleness of a limited number of structural members on the ductility of the entire structure

It is pointed out that in existing structures the requirements of capacity design, limitation of the axial force, local confinement, etc. have not been in general met. The implication of this is the difficulty in assessing a global behavior factor.

Summary

This entry deals with the seismic strengthening strategies for existing (code-deficient) ordinary structures. Reference to two regulatory texts that are compatible with each other, namely, the European Standard EN 1998–3 (2005) and the Greek Code of Structural Interventions (2012), has been selected as a basis for the presentation of the issue. These texts condense existing knowledge concerning the upgrading of ordinary structures and at the same time determine the procedure of the normative treatment of the issue.

First, clarifications on basic terms are given. Then, the general principles that rule the two aspects on which the issue of upgrading is based, i.e., assessment and redesign, are analyzed. Subsequently, the assessment and redesign objectives, which in general differ from those of the design of new structures, are presented.

The possibility of a variety of redesign objectives is introduced. High targets are proposed for a small, yet critical in terms of safety, group of buildings. On the contrary, there is a possibility, under certain conditions, to adopt lower targets for common existing buildings, in comparison to the targets for new buildings, with a view to a realistic treatment of the need for upgrading.

Furthermore, the general principles for pre- and post-earthquake intervention decisions are set, the methods of analysis and the conditions of their application are briefly presented, and, finally, the compliance criteria for assessment and redesign are described.

Introduction

The global seismic behavior of historic masonry buildings is highly influenced by the integrity of the connections among vertical and horizontal structural elements, to ensure the so-called box behavior. This, providing the transfer of inertial and dynamic actions from elements working in flexure out-of-plane to elements working in in-plane shear, leads to a global response best suited to the strength capacity of the constitutive

Seismic Strengthening Strategies for Heritage Structures,

Fig. 1 Correlation between knowledge level, analytical tools, risk representation, and interventions. credits: this publication D'Ayala Paganoni 2014

materials and hence enhanced performance and lower damage level. Notwithstanding the importance of connections' integrity, analytical checks of existing connecting elements, or design of new elements to strengthen existing connections, are generally based on qualitative rules or simplified overall checks, rather than rigorous analytical approach. The "Guidelines for Earthquake Resistant Non-Engineered Construction" were first published by the International Association for Earthquake Engineering (IAEE) in 1986 specifically with the objective of improving the seismic safety of non-engineered housing constructions.

A wide range of techniques and products for the seismic strengthening of heritage buildings are reported in the scientific literature and used in current practice to ensure the enhancement of existing connections. Heritage buildings require far more attention, especially when dealing with issues such as the compatibility between the chemical and mechanical properties of the strengthening system and the parent material. Many strengthening techniques, after an initial success and a strong commercial promotion, underperformed and showed unexpected drawbacks when put to the test of real seismic loading outside the controlled conditions of the laboratory environment. On the other hand, some existing strengthening systems can provide highly flexible applications and meet the expected requirements in terms of performance; some of these systems in fact draw on traditional

reinforcement techniques, with the addition of innovative materials and a deeper insight in the laws governing the dynamics of structures.

The choice of the most suitable strengthening system for a given building, however, is determined not only by the set of constraints of the specific project but, very importantly, by the framework used for its assessment. The EC8 part 3 or ASCE41-06, dealing with assessment, repair, and strengthening, introduce the concept of knowledge level as the determining factor for the choice of alternative assessment procedures involving diverse levels of resources. The diagram in Fig. 1 shows that there is a strict correlation not just between the representation of the seismic input and the type of analysis that can be carried out with it but also and most importantly between the input and the way risk is quantified and measured and between such measures and the principle on which possible strengthening interventions operate. Hence the level of knowledge and availability of data to carry out the assessment becomes critical in determining and fully designing the most appropriate strengthening solution.

Moreover, although European and national codes (e.g., Italian Ministry of Cultural Heritage and Activities 2006) suggest the use of various systems for the strengthening of connections, for example, ring beams, no detailed reference is made to specific procedures for the dimensioning and checks of such elements. The only indication

in this sense can be found in Section 6.1 Retrofit Design Procedure for existing building of Eurocode 8 ([EN 1998-3:2005](#)), which states that the design process should cover:

1. Selection of techniques and/or materials, as well as of type and layout of intervention.
2. Preliminary sizing of additional structural parts.
3. Preliminary calculation of stiffness of strengthened elements.
4. Analysis of strengthened structure by linear or nonlinear analysis. The typology of analysis is chosen depending on the level of knowledge regarding the geometry detailing and materials of the structure.
5. Safety verifications for existing, modified, and new structural elements carried out by checking that the demand at three different limit states – damage limitation, significant damage, and near collapse – is lower than the structural capacity.

In the safety verifications, mean values of mechanical properties of existing materials derived from in situ tests and other sources of information, like available documentation or relevant sources, shall be used, taking into account the confidence factors (CFs) specified in 3.5 of Eurocode 8 ([EN 1998-3:2005](#)). Conversely, for new materials, nominal properties shall be used without modification by confidence factor. The code also states that in case the structural system, comprising both existing and new structural elements, can be made to fulfill the requirements of [EN1998-1-2004](#), the verifications may be carried out in accordance with the provisions therein.

This last sentence indicates that for systems such as reinforced concrete (RC) ring beams or corner confinement, reference can be made to the specifications for RC members in the relevant sections of EC8 and other Eurocodes. However, this leaves open the problem of quantifying the interaction between original and new structural elements, and the assessment of the global seismic performance of the strengthened structure will still be affected by a large number of uncertainties.

The last 15 years have seen a steep increase in the use of new technologies for strengthening heritage buildings. Such fast development, as well as the high level of expertise and financial resources required for their application, often results in lack of standardization. Innovative technologies have not been extensively applied and validated in real-life situations yet, and the retrofit of a complex, precious building by means of unconventional systems is a difficult task that goes beyond the standard conservation practice. In fact, looking at the current scientific literature, it is clear that many projects of restoration and upgrade of monumental buildings are carried out by research organizations within the framework of specific projects or by large enterprises that specialize in the production and design of strengthening devices.

On the other hand, the lack of appropriate standards and procedures can be blamed for the incorrect application of some innovative strengthening techniques, notwithstanding recognized effectiveness and other benefits. One exception to this situation is the case of fiber-reinforced polymers for which guidelines and standards have been produced for selected countries (see, for instance, [CNR-DT 200/04](#), [CNR-DT 200R/13](#)).

In the following an overview of methods to structurally strengthen the masonry elements of historic buildings is given, pointing out the advantages and pitfalls of each system and the fundamental physical parameters and design process required. Available design procedures are reviewed and referenced, when available, to the writers' knowledge. The systems reviewed are applicable mainly to stone or brick masonry structures with timber floors and roof or with vaulted structures. The concepts underlying these methods are also usually applied to the strengthening of earth structures, although some of the details of the specific applications might differ due to the specific characteristics of the parent material.

The effective strengthening of a heritage building also relies on a correct redistribution of the inertia forces among vertical elements. For this to occur, the floor structures need to be acting

as a whole and ensure diaphragm action. While there is a wealth of research and methods to assess and strengthen historic and traditional floor structures to ensure they develop such action, these are not currently included in this chapter.

Base isolation is also increasingly becoming a proposed option for the retrofitting of historic buildings; however, actual implementations are still very rare and very expensive. This technique is also not treated in this current edition.

In this current edition, only methods suggested in the Eurocodes or methods related to recent technological developments are included. Many traditional “vernacular” methods of strengthening historic building exist in earthquake-prone countries and some have been studied in detail. These are not addressed here either.

Strengthening systems are reviewed depending on the type of enhancement achieved, i.e., whether there is an increase in strength, a control of deformation and displacement, or a dissipation of energy.

Connections Between Vertical and Horizontal Macroelements

The Eurocode 8 states that to improve connection between intersecting walls, use should be made of cross-bonded bricks or stones. The connection can be made more effective in different ways (EN 1998-3:2005):

- I. Through construction of a reinforced concrete belt
- II. By addition of steel plates or meshes in the bed joints
- III. Through insertion of inclined steel bars in holes drilled in the masonry and grouting thereafter
- IV. Through post-tensioning

The addition of steel ties, along or transversely to the walls, external or within holes drilled in the walls, is an efficient means of connecting walls and improving the overall behavior of masonry buildings (EN 1998-3:2005).

In the following we review:

- Stiffening of the wall system by corner and T-junctions confinement of wall panels achieved by inserting vertical concrete columns or steel meshes, fiber-reinforced horizontal strips, and polypropylene meshes
- Stiffening of the wall and floor system and connection to the horizontal structures by ring beams
- Connection of the walls and floor system by anchorage systems
- Improvement of the performance of the wall system by including energy absorbers and dissipating devices to connect the walls

The design of effective connections between various structural elements of a masonry structures is a critical step for the achievement of a good structural response in case of seismic events. Current codes provide for carefully designed and detailed connections; for instance, the Eurocode states that: “Floor systems and the roof should be provided with in-plane stiffness and resistance and with effective connection to the vertical structural systems (EN 1998-1:2004).”

This rule is also applicable to interventions on existing structures as the Eurocode indeed states that: “The connection between the floors and walls shall be provided by steel ties or reinforced concrete ring beams (EN 1998-1:2004)” and “Specifically for masonry structures: non-ductile lintels should be replaced, inadequate connections between floor and walls should be improved, out-of-plane horizontal thrusts against walls should be eliminated (EN 1998-3:2005).”

Moreover, in relation to the connections between walls and floors, EN 1998-3:2005 states that: if existing tie-beams . . . are damaged, they should be repaired or rebuilt. If there are no tie-beams in the original building structure, such beams should be added.

Improvement of connections between vertical and horizontal structures can be achieved through a variety of methods, which are described in the following.

Seismic Strengthening Strategies for Heritage Structures,

Fig. 2 Example of column tie (From <http://www.know2do.org/Retrofit/BrickMasonry/RSBrickMasonryP.htm>)

Confinement at Walls Junctions: Strength Enhancement

Column Ties

By confining plain masonry walls with vertical elements placed at all corners and wall intersections, as well as along the vertical frame of large openings, the seismic performance of a masonry building is improved as a result of the enhanced integrity of the structural system (Tomažević, 1999). This effectively changes an unreinforced masonry structure in a confined masonry structure. The disruption is significant and can affect very substantially the heritage value of the building. Moreover, such a technique is suitable only when horizontal RC tie beams in the bearing walls at floor level (see this IS section “Confinement at Wall to Floor Junctions: Ring Beams”) and stiff, monolithic floor diaphragms are in place; otherwise, the effect of the vertical confinement is scarce, or null, as shown by analysis conducted by Karantoni and Fardis (1992). Creation of corner confinement by column ties is not recommended for stonework masonry (Tomažević 1999).

For the construction of the confinement elements, all the bricks in the intervention area are removed; the concrete of the existing tie beams is also removed to allow for the connection between existing and new reinforcement. Vertical rebars and stirrups are placed and concrete cast (Fig. 2).

Tie columns should be as thick as the wall where they are located, although in many cases of repair of existing buildings, they are of reduced dimensions due to on-site constraints. Furthermore, they may sometimes be replaced by sets of reinforcing bars placed in holes drilled in the masonry and connected to the surrounding substratum by stirrups.

The confinement prevents disintegration and improves ductility and energy dissipation of URM buildings but has limited effect on the ultimate load resistance (Chuxian et al. 1997). However, the real confinement effect mainly depends on the relative stiffness between the masonry wall and the surrounding resulting concrete frame. Before cracking, the confinement effect can in general be neglected (Chuxian et al. 1997; Karantoni and Fardis 1992). For very squat URM walls (geometrical aspect ratio

of 0.33 and double fixed boundary conditions), the confinement increased the cracking load by a factor of 1.27 and the ultimate lateral capacity by a factor of 1.2 (Chuxian et al. 1997). For walls with higher aspect ratio, the confinement increased the ultimate capacity by a factor of 1.5. In addition, the confinement improved the lateral deformations and energy dissipation by more than 50 %.

The dimensioning procedure for column ties can be derived from the prescriptions specific to confined masonry structures. The process can be summarized as follows:

- Calculation of the appropriate combination of static and seismic loads acting on the structural elements (EN 1991-1-1:2002 and EN 1998-1:2004)
- Dimensioning and verification of the column ties for both static and seismic loading following the prescriptions provided for confined masonry structures (EN 1996-1-1:2005 and EN 1998-1:2004)

Special care should be taken in realizing the connection between the column ties and the horizontal structures in order to ensure a monolithic behavior of the resulting RC frame.

A much cheaper solution to confining masonry walls is achieved with Welded Wire Mesh (WWM). This consists in deploying a steel mesh on the two sides of a wall and around the corners, connecting it with bolts and then concrete over, by either shotcreting or other forms of plastering. The anchorage of the mesh to the foundation and horizontal structures is fundamental to achieve proper action transfer during shaking. Although less destructive than the construction of column ties, the system seriously affects the breathability of the walls and may cause deterioration due to moisture entrapment. The thickness of this reinforced plaster may vary between 25 and 100 mm depending on the regularity of the walls underneath. It cannot be applied in the presence of historic plasters or other valuable finishes. Its effectiveness highly depends on the relative stiffness between the original wall and the added layers.

Confinement by Fiber-Reinforced Plastic Strips

The application of fiber-reinforced polymer (FRP) material to the strengthening of masonry structures has to an extent mimicked application to RC structures. As a result, there are numerous examples in the literature relating to the confinement of masonry columns (e.g., Di Ludovico et al. 2010; Corradi et al. 2007). In the case of junctions between walls, horizontal strips of FRPs bonded at various levels along a masonry panel and anchored to the side walls can be used to restore corner connections, thus preventing overturning of façade walls. Optimal application is achieved when the whole perimeter of the structure is confined. Application of such techniques entails the removal of existing plaster and other superficial finish as a strong bond of the FRP strips to the masonry is necessary to ensure effectiveness of the system. The strips also need to be protected from UV radiations to prevent material deterioration. Their implementation might cause substantial loss of heritage value, and it is not recommended when valuable finishes are in place.

For the confinement to be effective, strips should be laid both horizontally and vertically. Tests by Hamoush et al. (2001) on walls strengthened with vertical and horizontal strips showed the effectiveness of the FRP systems as out-of-plane flexural strengthening elements, while Tumialan et al. (2001) have investigated the potential of near surface-mounted GFRP rods embedded into epoxy-based paste in the bed joints as shear enhancement. Cyclic testing of walls strengthened with vertical and horizontal GFRP or CFRP strips was performed by Marcari et al. (2003) and by Krevaikas and Triantafillou (2006). Those tests have highlighted a general decrease in strength and ductility of the confined members with the increase of the aspect ratio of the confined cross section. This is due to a reduction in ultimate strain at failure when increasing the aspect ratio. Glass fibers are more effective than carbon fibers, owing to lower stiffness. However, its effectiveness in connections between orthogonal walls has not been tested to the authors' knowledge. Issues of debonding should be thoroughly investigated on a case by

Seismic Strengthening Strategies for Heritage Structures, Fig. 3 Static scheme for the calculation of the tensile capacity of FRP strengthening to prevent overturning of front wall (CNR-DT 200/04)

case basis as failure mode and extent will be highly affected by the integrity and mechanical characteristics of the parent material external strata in relation to the composite characteristics.

FRP confinement is dimensioned by verifying:

1. The tensile capacity of the composite material
2. The capacity of the anchorage area

In detail this is done by (CNR-DT 200/04):

1. Checking that:

$$F_d \leq 2F_{Rd} = 2(A_f \cdot f_{fd}) \quad (1)$$

where

F_d is the design action applied to the FRP stripes by the front wall undergoing overturning caused by seismic equivalent action Q_d ; this is calculated by:

$$F_d = \frac{1}{2h^*} (Q_d h - N_d t - P_d t) \quad (2)$$

Dimensions and weight involved in the overturning mechanism are shown in Fig. 3:

F_{Rd} : design tensile capacity of the FRP strengthening

f_{fd} : design ultimate strength of the FRP strengthening

h^* : distance between level where FRPs are bonded and bottom hinge

A_f : FRP area

2. Checking the rip-off of FRP stripes from side walls:

$$F_d < 2F_{pd} = 2(A_f \cdot f_{pd}) \quad (3)$$

where

F_d is calculated as above.

F_{pd} is maximum anchorage capacity of FRP to one of the two side walls.

f_{pd} is design debonding strength of FRPs.

A_f is FRP area.

The second check is generally more demanding than the first, but it is not needed when full confinement of the structure is achieved by wrapping FRP stripes around the whole perimeter of the building and a suitable anchorage length is ensured (CNR-DT 200/04). Anchorage length should be at least 300 mm; otherwise, mechanical fixings can be used; however, the guideline does not specify suitable types and the procedure for sizing and positioning the fixings.

Additional calculations of the strengthened structure are necessary to ensure that the strengthened structure will be able to withstand other actions, such as the increased in-plane shear loading, now transferred from the walls

Seismic Strengthening Strategies for Heritage Structures, Fig. 4 Corner confinement of masonry walls by use of SRP strips anchored with SRP connectors (Photo Paolo Casadei 2008, product FIDSTEEL)

Seismic Strengthening Strategies for Heritage Structures, Fig. 5 Procedure for installation of PP meshing: (a) PP-band mesh, (b) detail of top/bottom

connection, and (c) retrofitted wall before application of final layer of mortar (Mayorca and Meguro 2004)

orthogonal to the walls parallel to the action. This should be done according to the specific indications of codes dealing with masonry structures in general.

Of course in order to prevent damage in the historic building, the capacity of the strengthening system needs to be less than the shearing capacity of any masonry course in the façade wall. Given the absence of ductility in the fiber composite, this system also presents the fundamental drawback of brittle failure, modest ductility, and relying on the damaging process of the masonry for energy dissipation. An improved version in this respect is provided by SRP strips, strips reinforced with steel, which show a greater ductility (see Fig. 4).

Confinement by Polypropylene (PP) Mesh

PP meshing uses common packaging straps (PP-bands) to form a mesh, which is then used to encase masonry walls, preventing both collapse and the fall of debris during earthquakes. PP-bands are commonly used for packaging and are therefore cheap and readily available while

the retrofitting technique is simple and suitable for local builders. PP meshing was developed by Meguro Lab, Tokyo University, and has had application in Kashmir and Nepal.

The retrofitting installation procedure is as follows (Mayorca and Meguro 2004):

1. The PP-bands are arranged in a mesh and connected at their crossing points (Fig. 5a).
2. Two steel rods are placed at the edges of the mesh; these bars are used to anchor the mesh at the foundation and at the top edge of the wall (Fig. 5b).
3. The walls are cleaned and, if possible, the paint is removed. Any loose brick is removed and replaced.
4. Six millimeter diameter holes are drilled through the wall at approximately 250–300 mm distance. The holes are cleaned with water spray or air.
5. The meshes are installed on both sides of the wall and wrapped around the corners and wall edges. An overlapping length of approximately 300 mm is needed.

6. Wire is passed through the holes and used to connect the meshes on both wall sides. In order to prevent the wires from cutting the PP-band mesh, a plastic element is placed between the band and the wire. Connectors are placed in proximity of the wall intersections and of the wall edges.
7. The top and bottom edges of the mesh are glued to the foundation and top of the wall by epoxy resin. The epoxy is used to connect the bars and the wall and it is not directly applied to the mesh. The bands, which are rolled around the bars, transfer their load through friction.
8. The overlapping parts of mesh are glued together so as to ensure the continuity of the strengthening (Fig. 5c).
9. A layer of mortar is laid on top of the mesh to protect it from UV radiation and rain and also to provide further bond.

Shear tests on walls strengthened by PP mesh (Mayorca and Meguro 2004) showed that although the strengthening does not increase the peak strength, it contributes to improving the structural performance after crack occurrence. The strengthened walls exhibit larger post-peak strength, while the mesh helps to spread the diagonal cracks over a wide region. The presence of connectors and the mortar layer, ensuring bond to the masonry, are critical to the performance of the wall.

Confinement at Wall-to-Floor Junctions: Ring Beams

A ring beam is a structural element built on top of the masonry structure to the purpose of:

- Creating a continuous connection between the roof structure and walls to better distribute the vertical loads
- Improving the connection between orthogonal walls and the three-dimensional behavior of structure

Reinforced concrete (RC) ring beams have been widely used for the retrofit of masonry structures from the aftermath of the Friuli, Italy

1976 earthquake onwards. The construction of RC ring beams involves:

- Consolidating the top part of the existing masonry by injections
- Drilling vertical holes and inserting steel rods for the vertical connection between the masonry and new element
- Building the formwork and placing the reinforcement of the beam
- Casting the concrete

Such system improves the seismic capacity of structures by:

- Distributing the vertical loads
- Transferring the horizontal loads from the floors to the bearing walls
- Connecting the bearing walls so as to create a boxlike behavior and prevent out-of-plane failure

However, during a seismic event, the high stiffness of RC beams may induce out-of-plane bending of the portions of wall between the restrained floors (Borri et al. 2009) with consequent bulging of walls and activation of out-of-plane damage mechanisms. Furthermore, such technique is often time-consuming, not cost-effective, and adds mass to the structure, which increases the earthquake-induced inertia forces and consequently requires strengthening at the basis of the walls.

All these collateral effects represent major drawbacks for heritage buildings due to the large deformability and scarce cohesion of historic masonry as opposed to the high stiffness and weight of reinforced concrete. Moreover, the construction of a ring beam has a high impact from the aesthetic point of view and may require the removal of large portions of the original material of the walls and of part of the structure of the roof.

Indeed, several surveys carried out in European historic centers after earthquakes (e.g., Spence and D'Ayala 1999; D'Ayala and Paganoni 2011) highlighted how RC beams with poor connections to the underlying material

negatively affected the buildings rather than improving its structural response. Damage generally consisted of a shear failure at the interface between roof ring beam and wall, with more or less extensive damage to the masonry and eventual collapse of walls.

Nevertheless, the use of RC ring beam is allowed for the connection between walls and roof structure (Italian Ministry of Cultural Heritage and Activities 2006), providing that the dimensions of the ring beam itself do not cause an excessive increase of mass. However, conversely to steel ring beam, the use of RC beams for the strengthening of the connection between walls and intermediate floor structures is advised against (Ministero dei Beni Architettonici e Culturali, Italia, 2006), as it is far too invasive and deeply affects the performance of the structural system.

The 2007 edition of the California Historical Building Code (2007), instead, generally recommends the use of tie beams but does not specify the use of reinforced concrete.

In the scientific literature, references to procedures for the sizing of reinforced concrete ring beams can be hardly found, and it is highly likely that in common practice a large majority of additional concrete elements are simply dimensioned by the rule of thumb, using standard geometry and amount of reinforcement of ring beams in RC frames.

An improvement on RC ring beams are reinforced masonry ring beams, combining good quality brickwork (generally made of solid bricks) to steel or composite reinforcement bonded together by a binder-like grout (Ministero dei Beni Architettonici e Culturali, Italia, 2007).

In the case of steel reinforcement, the brickwork of the ring beam is laid leaving an internal cavity where the reinforcement bars and stirrups are positioned before casting the mortar-crete.

The creation of a reinforced masonry ring beam aims to:

- Provide a continuous connection between the roof structure and walls to better distribute the vertical loads.

- Improve the connection between orthogonal walls so as to enhance the three-dimensional behavior of structure.

The advantage of the technique in respect to RC ring beams is that stiffness and mass are closer to the original masonry. A RM ring beam has also good vertical deformability, and therefore it spreads the vertical load to the masonry beneath. Furthermore, it has a lower aesthetic impact, as the additional element can match the appearance of the original masonry.

RM beams are realized by:

- Building two wallets of brickwork or stonework on top of the existing wall, leaving a cavity between the two
- Placing reinforcement bars within the cavity
- Casting the concrete within the cavity, as to create a beam

Steel plate and transversal bricks connect the outer wallets.

In some cases, consolidation of the masonry under the ring beam by injections is needed to ensure a sufficient shear capacity and similar stiffness.

Like in the case of RC ring beams, examples of the sizing of RM ring beams can be hardly found in the scientific literature.

A systematic dimensioning procedure for RM ring beams could be derived from the prescriptions specific to RM structures. The process can be detailed as follows:

- Calculation of the appropriate combination of static and seismic loads acting on the structural elements (EN 1991-1-1:2002 and EN 1998-1:2004).
- Dimensioning and verification of the beam for both static and seismic loading following the prescriptions provided for reinforced masonry structures (EN 1996-1-1:2005 and EN 1998-1:2004). This is done because a RM ring beam is in fact a bearing element and should therefore be calculated for vertical loading as beams are. Furthermore, the RM ring beams should be dimensioned for tensile load as the confining

Seismic Strengthening Strategies for Heritage Structures, Fig. 6 Example of steel cord used in SRG (Borri et al. 2007)

action of the beam consists indeed in resisting the thrust generated by walls that separate under horizontal actions; this is done by ignoring the cross-sectional area of concrete and masonry and sizing the steel reinforcement so that it can bear the whole in-plane action.

- Dimensioning and checks of metallic connectors for both static and seismic loading (EN 1993-1:2005).
- Dimensioning and checks of connection of the metallic fasteners to the concrete element of the beam for both static and seismic loading (EN 1992-1-1:2004 – Section 8 Detailing of Reinforcement; DD CEN/TS 1992-4-1:2009).
- Dimensioning and checks of connection of the metallic fasteners to the masonry of walls for both static and seismic loading.
- Dimensioning and checks of connection of the metallic fasteners fixed to the timber elements of the roof for both static and seismic loading (EN 1995-1-1:2004 – Section 8 Connections with Metal Fasteners).

Borri et al. (2009) propose a system combining FRPs and steel-reinforced grout (SRG), the latter made of high strength steel wires forming cords (Fig. 6) embedded in a cementitious grout. The ring-beam system, called LATLAM, is obtained by overlapping several layers of bricks and laminates embedded within a polymeric matrix or a cementitious grout (Fig. 7). By superposition of blocks and composite sheets, it is possible to achieve a structural element of any size and length,

Seismic Strengthening Strategies for Heritage Structures, Fig. 7 Assembly of LATLAM ring beam (Borri et al. 2007)

similarly to glue-laminated timber beams. The assembly acts as a single structural element and combines the compressive strength of masonry units with the good tensile properties of composite materials, avoiding the problem of the increase of mass typical of RC ring beams. A simplified model for the evaluation of the ultimate strength of a LATLAM section under bending stresses is available in Borri et al. (2007). The collapse is assumed to occur by crushing of masonry.

Strengthening by Way of Ties: Displacement Control

The insertion of ties to connect walls to walls, walls to floor, or walls to vaults is a traditional system, still in large use nowadays.

Post earthquake observation, experimental evidence and computational results, all show that crossties installed at the intersection of perpendicular sets of walls are able to prevent the overturning of whole façades without interfering with the original structural layout (Tomaževič 1999) (D'Ayala and Yeomans 2004; D'Ayala and Paganoni 2011).

For the ties to be effective, proper anchorage within or against the masonry is necessary. This might be achieved, either by using end plates or by using grouted ends. The tie is usually a passive element which becomes active when cracks open between orthogonal walls or timber beams tend to slide off their seat.

Seismic Strengthening Strategies for Heritage Structures, Fig. 8 Examples of metallic ties with end plates (Giuffrè 1993)

The dimensioning procedure of metallic ties connecting timber joist to walls can be derived from the prescriptions specific to steel structures. The process can be detailed as follows:

- Calculation of the appropriate combination of static and seismic loads acting on the structural elements (EN 1991-1-1:2002 and EN 1998-1:2004).
- Dimensioning and checks of the ties following the prescriptions provided for steel structures (EN 1993-1-1:2005).
- Dimensioning and checks of connection between metallic elements and timber elements of the horizontal structure (EN 1995-1:2004).
- Dimensioning and checks of connection of the metallic elements to masonry. Depending on the type of connection – by binder or by mechanical locking – checks should be performed in a different way as discussed in the next two subsections.

In the case of ties connecting masonry to masonry point c is not relevant. However, it

might be important to proceed to a local consolidation of the masonry by use of mortar grout before implementing the tie. The major pitfall of cross-ties is the possibility of pullout damage at the head of the anchorage due to the different deformabilities of anchor and masonry. The use of high-ductility systems recommended by codes would overcome this issue, thus achieving the objective of protecting culturally valuable finishes and preserving life and safety.

Ties with End Plates

The dimensioning process of metallic ties with end plates (Fig. 8) consists in:

- Sizing the cross section of the metallic rod to resist the axial load deriving from the pulling action of the portion of wall constrained by the tie in case of out-of-plane action. The minimum diameter of the rod is calculated by (Tomažević 1999):

$$D_{\min} = \sqrt{\frac{H_{u, \text{seg}}}{n} \frac{4}{\pi} \frac{1}{f_y}} \quad (4)$$

where

$H_{u,seg}$: ultimate seismic resistance of a critical part of a building,

n : number steel ties,

f_y : yield stress of steel.

The horizontal load that activates the overturning mechanism in a portion of wall, $H_{u,seg}$, needs to be equilibrated by the action of cross-ties and can be calculated by limit analysis. The position of hinges and the collapse load factor, for the portion of wall involved in the out-of-plane mechanism, are calculated so as to satisfy rotational equilibrium and the distribution of stress assumed in the masonry section at collapse as shown in Fig. 9. In deciding the static scheme for the calculation of the mechanism, the type of connections should be considered as they influence the constraints of the ideal beam that represents the wall: for instance, a wall with no positive connections to the floor structures can be modeled as a cantilever, while the positive effect of well-connected horizontal structures should be accounted for by using a simply supported beam scheme.

- Sizing the end plate to prevent punching failure. This is done by verifying that the tensile strength of the parent material is sufficient to withstand the 45° component of the axial load acting on the tie. The rupture surface to consider for the calculation of the acting stress is a conical/pyramid surface with sides inclined at 45° in respect to the plain of the wall (Fig. 10).

Ties Without End Plates

Anchors without end plates (Fig. 11) consist of a metallic profile that is embedded in the masonry and can transmit loads to the substratum by mechanical locking, friction, bond, or a combination of these three (Eligehausen et al. 2006), rather than use of an element such as a plate, a key, or a peg. Mechanical locking can be obtained, for instance, by undercut, namely, shaping the end part of the hole and introducing an anchor with an end shape so as to result larger than the rest of the shaft. Friction systems, instead, consist of torsion or displacement-

Seismic Strengthening Strategies for Heritage Structures, Fig. 9 Static scheme of multistory wall panel for determination of hinge position and collapse load multiplier (D'Ayala, Speranza, 2003)

expansion anchors, which are designed to introduce a radial pressure between the anchor and the hole. Finally bond systems rely on the use of a binding agent, which is either injected or released through a capsule system (Fig. 12).

A fairly common commercial product consists of metallic profiles shaped as a coil; such profiles can be dry screwed in the masonry, thus mainly relying on a mechanical and frictional mechanism, or injected with resins/grout, in which case they work through the bond established between masonry and binder. Another popular system, increasingly used in conservation, is formed by steel sections provided with a fabric sleeve; profiles are installed in holes and then grout/resin is injected in the sleeve, so that the sleeve molds itself to the spaces and voids in the wall and creates a system combining mechanical locking and bond. A further advantage of this latter system is the

Seismic Strengthening Strategies for Heritage Structures, Fig. 10 Rupture surface for the calculation of tensile strength acting on parent material and sizing of

the end plate in case of: (a) rectangular key or (b) circular end plate (<http://posterremoto.altervista.org/Dati/i.html>, last accessed 7th March 2011)

Seismic Strengthening Strategies for Heritage Structures, Fig. 11 Grouted anchor injection scheme (Gigla, Wenzel 2000)

Seismic Strengthening Strategies for Heritage Structures, Fig. 12 Post-installed anchors: (a) systems for the transmission of load to substratum. (b) Typologies of binding materials for bond anchors (Eligehausen et al. 2006)

control over the diffusion of the binder within the parent material, while the grout can expand to the cavity around the ties, particularly useful for rubble double leaf masonry.

A variety of materials, ranging from mineral binders to polymers, can be used as binder. However, materials based on polymers, such as epoxy or polyester resins, which are often used for concrete structures, should undergo careful assessment before use in historical masonry, due to possible issues regarding the mechanical and physical compatibility. Much more common for the repair of historical buildings are mineral binder systems based on cement or hydraulic lime with the addition of admixtures and fillers or aggregate. To inject bore holes, usually pure water/binder systems are used with typical w/b values of 0.8–1.0. However, the w/b ratio has to be adjusted according to the volume to be injected and to the moisture content of the substrate.

Post-installed anchors are a very common method for the strengthening of historic masonry since they allow for a wide range of applications, from restoring the through-thickness cohesion of multilayered masonry to the increase of tensile and shear capacity of panels; furthermore, they can be used at the joints between structural elements either in the form of short connectors or as longitudinal elements. These latter have the same function as metallic crossties, but, rather than relying on an end plate for the connection to the wall, pullout loads are transmitted by a shear mechanism – for friction and bond anchors – or through mechanical locking within the masonry itself.

The diameter of the anchors is chosen as a function of the expected pullout force applied, the tensile strength of the masonry, and the bond strength of the grout to masonry interface. Bonded anchors can be passive or active, i.e., prestressed or posttensioned. Passive anchors are used for up to 4 m in length; prestressed anchors can be used up to 35 m in length (Gigla and Wenzel 2000).

The installation of anchors is carried out by:

- Drilling holes in the parent material; due to the weakness and preciousness of the parent

material, dry/wet diamond rotary drilling rather than percussive drilling is recommended.

- Removing all cores from the bore hole and checking the depth. Removing dust and debris.
- Placing anchors and injecting the binder.

The anchors utilized are usually stainless steel, threaded rods, or special prestressing bars. The diameter of the hole drilled to accommodate the anchor is a function of the strength differential between parent material and grout and this and the steel itself. The bond of the anchor inside the masonry unit depends on the type and properties of the grouting material and on the type of masonry block units.

The failure mechanisms of injection anchors in masonry are discussed in Gigla (2004, 2010), based on an extensive test program of over 500 pullout tests. The studies consider five different failure modes including failure mechanisms related to the (a) poor strength of the injected grout, (b) exceeded tensile strength of surrounding parent material, (c) bond failure between the outer surface of the grout and the parent material, (d) a combination of b and c, and (e) failure of the steel or grout in tension (under-designed).

Recommendations for the design of injection anchors are given in Gigla (2004). The design value for the bond strength is computed as follows:

$$X_{A,d} = \frac{\Phi_f}{\gamma_m} \left(\frac{f_{G,c}^2}{500} + X_{B,w} \right) \quad (5)$$

$X_{A,d}$: Design value of bond strength, as a function of the compressive strength of grout and independent of bond length.

Required minimum bond length: $L_b = 150$ mm inside monolithic stone, $L_b = 190$ mm in bed or head joints of brick, and $L_b = 430$ mm in bed and head joints of blockwork.

$f_{G,c}$: Compressive strength of grout. Minimum value: $f_{G,c} = 16.6$ N/mm². Maximum value covered: $f_{G,c} = 38.7$ N/mm². A minimum

bending tensile strength of $f_{G,ct} = f_{G,c}/8 = 2.0 \text{ N/mm}^2$ is required.

$f_{G,ct}$: Flexural strength of grout obtained from standard.

Φ_f : Reduction factor for bond in bed or head joints, $\Phi_f = 0.5$.

$X_{B,W}$: Term indicating the increase of bond strength inside water-absorptive stone material. $X_{B,W} = 0.15 \text{ N/mm}^2$.

γ_M : Partial factor for property, recommended: $\gamma_M = 1.35$

The term $X_{B,W}$ considers the water absorption of the masonry substrate. Pullout studies revealed that materials with higher water absorption capacity yielded higher pullout strength than materials with low or no water absorption capacity.

Furthermore, the anchor capacity can be designed by first computing $R_{A,d}$ which refers to the bond capacity between grout and rod. The equation considers the ratio of bed and head joints of the borehole surface across bond length and limits $R_{A,d}$ to bond inside full stone sections ($A_B/A_{G,d} = 1$ completely in stone; $A_B/A_{G,d} < 1$ in joint):

$$R_{A,d} = X_{A,d} \cdot \frac{A_B}{A_{G,d}} \cdot A_{A,d} \quad (6)$$

with $R_{A,d}$, design capacity of the injected anchor; A_B , portion of the cylindrical surface of injected mortar grout made of stones or units; $A_{G,d}$, total cylindrical surface of injected mortar grout; and $A_{A,d}$, interface of tensile element and injected mortar plug (cylindrical surface of steel bar), calculated with nominal bar diameter and bond length. The design strength of the anchor shall be smaller than the tensile capacity of the surrounding masonry so as to cause failure by yielding of the metallic element and prevent brittle failure of the masonry. This threshold can be computed as

$$F \leq \frac{1.9 \cdot f_{B,t} \cdot L_b \cdot \pi \cdot d_B \cdot (h_s^2 - d_B^2)}{\gamma_M \cdot \tan(\varphi) \cdot (d_B^2 + h_s^2)} \quad (7)$$

where

F : anchor tensile force

$f_{B,t}$: tensile strength of surrounding stone

d_B : borehole diameter

h_s : minimal distance to edge of surrounding masonry

L_b : bond length

$\tan(\varphi)$: tangent of angle of friction for force transmission between anchor's grout and bore-hole, about 50° in water-absorptive material and about 60° in non-water-absorptive material

γ_M : partial factor of safety for stone tensile strength; recommendation, 1.5

While these values are appropriate for an axial pullout test, they do not apply to failures of anchors loaded in shear or bending as a result of relative movements between the structural elements that they reconnect. Furthermore, as the family of dowel anchors also includes short fixings such as pins and nail-like fixings, failures connected to loads transmitted from other elements and in proximity to edges or openings should also be analyzed, these being highly relevant to various typologies of strengthening, such as confinement or end plates, where the use of fixings is required but rarely regulated.

Whereas the dimensioning procedure of bonded anchors in concrete has been extensively studied and commented (Eligehausen et al. 2006) and European guidelines do exist (EOTA TR029 2010; EOTA TR045 2013; DD CEN/TS 1992-4-1:2009), anchors in masonry lack specifically dedicated codes or recommendations. Modes of failure and hence the procedure for dimensioning could be partly derived from DD CEN/TS 1992-4-1:2009. Possible modes of failure due to axial load may be bond between metal and binder or between binder and parent material; cone pullout of parent material, due either to the failure of bond in the mortar joints or to tensile failure of masonry units; and failure of steel, although this is highly unlikely unless the metallic section is severely under-designed. Possible modes of failure due to loading transversal to the anchor axis may be crushing failure of either the binder or the parent material, edge failure of masonry when the load is applied in proximity of openings and corners, pryout failure of parent material, or failure of steel for combined bending and shear action. Each of these failures is considered by the guidelines and the elements of the anchorage assembly dimensioned accordingly.

Other factors considered in the guidelines are the performance of anchors when undergoing fatigue loading and the dimensioning criteria for seismic loading. For anchors embedded in concrete, ductile failure is achieved by controlling the dimensioning of steel so as to avoid the fragile failure of the substratum, and this concept should be extended to masonry structures. However, prescriptions in [EOTA TR029](#), [EOTA TR045](#), and [DD CEN/TS 1992-4-1:2009](#) rely on a series of parameters, such as bond strength or minimum distance to edge, that should be either provided by the producer of the anchors or derived experimentally. In case of anchors for masonry, due to the lack of standardization as well as the variability of parent materials and masonry fabrics, not every producer is able to provide all the required information and extensive tests covering the full range of parameters needed are missing from the scientific literature.

Energy Dissipation Systems

Systems like crossties have been and are still commonly applied in rehabilitation practice throughout Europe for providing connection at the joints of perpendicular sets of masonry walls where out-of-plane damage is most likely to occur. Nonetheless pullout damage at the head of the anchorage and increased in-plane diagonal cracking may affect valuable finishes and precious frescoes.

The current codes encourage the use of these conventional stiffness-based systems ([EN 1998 Eurocode 8](#); Italian Ministry of Cultural Heritage and Activities [2006](#)) because innovative techniques drawing on performance-based principles (Priestley [2000](#)), despite their effectiveness in new structures, rarely meet the requirements of reversibility and low impact required for historic structures.

As widely experienced in many applications carried out in recent years, an effective alternative to conventional strengthening techniques is the use of passive energy control and dissipation techniques.

Energy dissipation systems indeed comply with the concept expressed in [EC 8 \(EN 1998-3:2005\)](#) that:

The selection of the type, technique, extent and urgency of the intervention shall be based on the structural information collected during the assessment of the building. The following aspects should be taken into account:

[..]

- d) Increase in the local ductility supply should be pursued where required;
- e) The increase in strength after the intervention should not reduce the available global ductility.

In the field of cultural heritage, such techniques must aim to enhance the seismic performance of structures as well as limit the aesthetic impact on the building and protect elements that, despite not being relevant to the structural behavior, have cultural and historic value.

Energy control systems can either provide the structure with additional dissipation capacity and/or reduce the amount of ground input energy transferred to the structure. However, base isolation systems require heavy interventions on the bearing structure (base cut, new foundation structure, etc.) and are therefore rarely suitable for the retrofit of heritage buildings.

Energy dissipation devices can instead be placed in a number of key locations within the structure where relative displacements between members are expected to occur; thus, from the point of view of intrusiveness, they do not differ from many other standard techniques. A suitable position for the installation of dissipative devices is at the wall-to-floor interface of masonry buildings, where relative motion can occur without impairing the global structural integrity.

Energy Absorbers

Benedetti ([2004](#)) developed a series of energy-absorbing devices for existing masonry buildings drawing on experimental results that had showed that the more energy is absorbed through damage by the noncritical elements of the structure, the later global failure occurs. The main requirements set for the devices were:

- Activation of the device for very low level of damage and cracking
- Sensitivity to both in-plane and out-of-plane movements

Seismic Strengthening Strategies for Heritage Structures, Fig. 13 RAG energy absorber: (a) prototype (Benedetti 2004); (b) setup in series with metallic crosstie installed on a masonry specimen (Benedetti 2004)

- Limitation of forces transmitted to the parent material at the fixings of the dissipative devices, so as to avoid localized damage and detachment of the devices

The RAG energy absorber (Fig. 13a) consists of four arms hinged at their end so as to form a square element. Hinges are made of lead cylinders press-fitted into the arms. When two (or four) of the corners of the device, which are connected to the masonry wall, displace relatively to each other as a consequence of damage in the parent material, the hinges deform plastically in torsion (in-plane action of the device) or bending (out-of-plane action of the device), thanks to the low yield strength of lead. Conversely, the arms are made of a stiffer material so as to remain in the elastic range. Besides a full characterization of the device, RAG energy absorbers were also tested inserted in full-scale masonry specimens on shaking table in an out-of-plane configuration (Fig. 13b), where the devices were used in series with traditional metallic crossties to connect two parallel walls. The holes that can be observed in the arms of the RAG device aim at reducing the weight of the element and avoiding a delay in the activation of the yielding mechanism. A pretensioning element was positioned in series with the anchor to further ensure the lack of any initial deformation in the crosstie.

Shock Transmission Units

STUs, or viscous dampers, consist of a hollow cylinder filled with fluid, this typically being silicone based. As the damper piston rod and piston head receive an impact, the fluid is forced to flow through orifices either around or through the piston head. The resulting differential in pressure across the piston head can produce very large forces that resist the relative motion of the damper, while the input energy is dissipated in form of heat due to friction between the piston head and fluid particles flowing at high velocities. Conversely, since this type of devices is velocity dependent, slow movements such as thermal expansions are allowed.

The viscous devices are characterized by a nominal strength: for high load rates and for input forces below their capacity, they show high stiffness; above it they feature a perfect plastic behavior, with dissipation of hysteretic energy in case of cyclic loads. The main drawback of this type of devices is the risk of leakage of the fluid, which involves the need for regular inspections and further costs involved with the maintenance of the dissipative system. Mandara and Mazzolani (2001) investigated two different methods for the dimensioning of viscous devices. In the Plastic Threshold Approach (PTA), devices are conceived and sized to limit the magnitude of force transmitted across connected

members to a maximum value, determined according to the design resistance of structural elements involved. Beyond this threshold, the hysteretic energy dissipation takes place, while below the threshold the behavior of structural members is virtually rigid, which ensures the maximum degree of redundancy to the structure under serviceability load conditions. According to the Optimal Viscous Approach (OVA), the interaction between connected members is controlled by the viscous properties of the devices, which are dimensioned so as to minimize the magnitude of the force acting on them independently from its value. Contrary to PTA, the connection between elements is never fully rigid, so that energy can be dissipated under moderate intensity earthquakes too.

Shape Memory Alloys

Shape Memory Alloys (SMAs) are metallic materials that show special thermomechanical properties due to a reversible transformation between two crystalline configurations, austenite and martensite, without degradation of the crystal structure.

For some SMAs, the phase transformation is temperature-correlated, while for others, such as nitinol (NiTi SMA), the phase change can be stress induced at room temperature.

The stress–strain curve, measured during a monotonic tension test on a NiTi SMA wire, shows:

- (a) An almost linear portion corresponding to the elastic deformation of the material in its austenitic phase.
- (b) A loading plateau due to the transformation in martensite.
- (c) A new elastic phase that initiates after the complete transition to the martensitic phase (whose upper boundary is called maximum superelastic strain).
- (d) A final plateau, related to the true yielding of the alloy, which ends with failure.
- (e) Stress removal causes a reverse phase transformation, where the material goes back to the austenitic phase, stable for lower load's values.
- (f) Strains are almost completely recovered. This property is known as superelasticity.

These characteristics make SMAs particularly suitable for use in seismic dampers, especially considering that some alloys, such as nitinol, have very good corrosion-resistance characteristics.

Shape Memory Alloy Devices (SMADs), which consist of metallic ties and groups of wires of SMAs, were developed within the framework of the ISTECH project (Indirli et al. 2001) and patented by Fip Industriale, Padova, Italy. Their application has featured in high-profile projects such as the repair and strengthening of the Upper Basilica of St. Francis in Assisi, San Feliciano cathedral in Foligno, and San Serafino Church in Montegranaro, Italy. In the Upper Basilica of St. Francis, 47 SMADs were used to connect the roof to the tympanum of the transept; the SMADs were connected on one end to a threaded bar attached to an anchorage plate in the façade and on the other end to a plate bolted to a counter plate embedded in the RC rib that was cast to stiffen the existing concrete roof (dating back to the 1950s). SMADs were three-plateau self-balanced devices of three different sizes, with design capacity ranging from 17 to 52 kN and maximum allowable displacement between ± 8 and ± 25 mm.

Dissipative Anchor Devices

Given the difficulty of ensuring ductile failures of anchors embedded in masonry, D'Ayala and Paganoni (2014) in collaboration with CINTEC International developed two prototypes of dissipative anchor devices to address the problem of out-of-plane mechanisms.

The devices are conceived to be inserted at the joint between perpendicular walls, as part of longitudinal steel anchors grouted within the thickness of the walls. Devices are designed to work in tension, similarly to traditional crossties, which experience axial loading when one wall panel tilts outwards as a consequence of ground acceleration. This type of installation ensures a low impact on the aesthetics of the building as it does not affect the finishes.

One device relies on the plastic behavior of steel and consists of a metallic element designed to achieve lower capacity than the standard tie to

Seismic Strengthening Strategies for Heritage Structures,

Fig. 14 Dissipative anchor devices: (a) hysteretic and (b) friction based (D'Ayala, Paganoni 2014)

which it is connected (Fig. 14a). The second device (Fig. 14b) is made of a set of small plates; bolts are used to apply a perpendicular pressure creating friction and adjusting the level of slip load beyond which relative sliding occurs. Specially designed stops ensure that the sliding motion remains in the desired range.

While the metallic profiles improve the box-like behavior of the building, contributing to an increase in stiffness that improves the structural response to low excitations, the devices allow small relative displacements between orthogonal sets of walls; additionally, for higher horizontal loads, they dissipate part of the energy input into the structure so that problems of localized damage can be avoided. Therefore, the design focuses on control of displacements and reduction of accelerations and stress concentration.

The two dissipative devices have been validated by cyclic pseudo-static and dynamic tests on the isolated devices and by pullout tests on the devices anchored in series to a conventional post-installed anchor embedded in low-shear capacity masonry (D'Ayala and Paganoni 2014).

Experimental results confirmed that both the yielding and frictional elements are able to provide the anchorage with ductility and prevent damage to occur in either the grouted sleeve or the masonry, while traditional anchors, which were tested for comparison purposes, display a

high stiffness and fail at the interface between grout and parent material or in the masonry units. In the case of friction devices, it was observed that, due to tolerances of the pieces composing the assembly, a locking phenomenon occurred for the higher levels of perpendicular pressures; consequently, load-deflection curves feature additional stiffness in respect to the flat branch typical of a friction mechanism. Such behavior will need to be corrected so that the device can provide homogeneous performance over the required range of perpendicular forces.

The dimensioning procedure is based on the idea that a strengthening system can be divided into subcomponents to which one type of failure controlled by a single parameter can be associated. These parameters can be used in the formulae prescribed by design codes to calculate the capacities of components and hence determine the hierarchy of failure. The parameter values can be obtained via a number of sources: producers' specifications, recommended or limit values provided by codes, and, if any, laboratory and/or on-site tests.

Table 1 exemplifies the procedure for the calculation of the tensile capacity of the dissipative anchoring devices in series with a grouted metallic anchor. Maximum capacity is reached if one of the components fails or when the dissipative device is activated. Further checks can also be

Seismic Strengthening Strategies for Heritage Structures, Table 1 Design of dissipative anchors: parameters that identify the tensile capacity, value range achieved during experimental validation, and range prescribed/recommended by design codes (From D'Ayala and Paganoni 2014)

5) $f_{masonry}$: Shear strength of parent material [N/mm ²] 	This type failure, although expected, did not occur during experimental campaigns	Calculated as: $f_{masonry}=f_{vk}=f_{vk,0}+0.4\sigma_d$ (EN 1996-1-1:2005). In the tested case it would be expected: 0.52 MPa 0.27 MPa The failure surface, A_f , is a truncated cone with smallest base corresponding to the drilled hole, apothem inclined at 45° and height equal to the wall thickness																								
6) $f_{masonry}$: Tensile strength of parent material [N/mm ²] 	A "wrench" failure occurs instead of the expected "cone pull-out" failure. Failure surface, A_f , develops along vertical joints. $f_{masonry}=f_{nt}=0.67$ MPa (from wrench test)	No mention about this type of failure has been found in the technical literature or design codes.																								

performed in terms of displacement and ductility, as discussed in the following.

The demand in terms of tensile capacity of metallic anchors is calculated as:

$$F_D = M \cdot a_i \quad (8)$$

where

M : mass of structure that bears on the i th anchor of the strengthening system. M depends on the geometry and construction arrangement of the building, including horizontal structures, and on the layout of the set of anchors to be designed.

a_i : horizontal acceleration experienced by the mass M . An estimate of the natural period of the system can be used to determine the correct design spectral ordinate and the distribution of amplification over the height of the structure. An accurate estimate of the acceleration at the height of the anchor can be obtained either by using the first natural modal shape or the procedure proposed by Miranda and Taghavi (2005).

The reference acceleration is calculated as function of the three limit states defined in EN 1998-3:2004, so that the design demand is:

- F_{DNC} : near collapse, calculated for a seismic action with a probability of exceedance of 2 % in 50 years
- F_{DSD} : significant damage, calculated for a seismic action with probability of exceedance of 10 % in 50 years
- F_{DDL} : damage limitation, calculated for a seismic action with probability of exceedance of 20 % in 50 years

All the subcomponents of the strength-only portion of the anchor assembly are brittle or, in the case of the grouted steel elements, are not supposed to experience large deformations; therefore, they are dimensioned in terms of strength for near collapse limit state, according to EN 1998-3:2004. The minimum capacity in the assembly must be:

$$\text{Min}(F_{\text{steel}}, F_{a/b \text{ bond}}, F_{b/p \text{ bond}}, F_{\text{masonry}}) > F_{DU} \quad (9)$$

Capacities are calculated using information in the relevant row in Table 1. It is important to notice that while certain values in Table 1 are generally applicable, others are not: the standardization of steel production ensures highly repeatable performance, whereas bond strength, for instance, largely varies depending on the substratum. Therefore, it is advisable that tests be performed each time; if this cannot be done, lower limit values provided by the code and reported in Table 1 can be used.

Table 1 does not include the connections' anchor/dissipative devices and the stops of the friction device. However, these components should also be dimensioned to resist F_{DNC} as also required by EN 15129:2009.

The dissipative elements of the devices, either hysteretic or frictional, are designed to be activated at the threshold of damage limitation, when cracks start opening and allow for the dissipative elements to become active. When the hysteretic devices enter the plastic field, or the friction devices start sliding, the connection between wall panels is still maintained, but the pullout of the head of the anchorage is prevented and drift controlled.

Hence, from the point of view of force design, depending on which dissipative device is used, the following requirements apply:

$$\begin{aligned} F_{\text{yield}} &= F_{DD} \text{ or} \\ F_{//} &= F_{DD} \end{aligned} \quad (10)$$

where F_{yield} is the yielding capacity of the hysteretic device and $F_{//}$ is the slip load of the frictional device.

The dissipative devices should also comply with requirements for interstorey drift of buildings undergoing seismic action. The chosen value of maximum allowable drift, $d_r = 0.003$, for damage limitation is taken from OPCM (2005) which provides drift limits for damage limitation in walls of masonry buildings. This limit is also in line with the expected drift stated in FEMA 356 (BSSC 2000) for unreinforced masonry buildings at the limit state of immediate occupancy.

For historic buildings, the allowable drift is increased by using the reduction factor $\nu = 0.4$, which is taken from [EN 1998:2004](#) and accounts for the fact that devices are designed to be used in heritage structures, which fall in the importance category III of Eurocode 8 ([EN 1998:2004](#)).

It is therefore

$$d_r = \Delta_e < 0.003 \cdot h/\nu \quad (11)$$

where

Δ_e : the elongation of the device before yielding, in case of the hysteretic device, or before activation of the friction mechanism, in case of the frictional device,

h : interstorey height, or vertical distance of installation of anchors. A standard distance of 3 m has been assumed in the calculations, but anchors might need to be spaced more closely along the height of the wall to prevent substratum failures.

The first threshold of the hysteretic device, identified at 0.5 % elongation of the dissipative element, coincides with 46 % of the hysteretic device load capacity. The second threshold, at 5 % elongation and 72 % maximum load, should instead be used to verify the capacity of the dissipative device for the limit state of significant damage, so that dissipation of energy is ensured during low-to-medium seismic excitations. Beyond this limit, the device has a further margin of safety given by buckling, meaning that the device can reach the limit of near collapse with damage, but not complete failure, and it could still be substituted, as it has been proved by experimental testing and in response to the requirements of [EN 1998:2004](#).

In the case of a frictional device, the drift limit is ensured by default because: before activation of the friction mechanism, deformations are negligible and, beyond activation of sliding, the device displacement is limited by the assembly stops. The device can therefore perform for all limit states, as long as the connections and stops in the assembly are designed to resist up to the state of near collapse.

Summary

In the last decades, a number of technical solutions for the improvement of structural connections have been developed in response to the increasing demand for strengthening systems specifically designed for the protection of heritage assets from earthquake-induced damage.

Notwithstanding recommendations from seismic standards and conservation codes of practice, and the availability of alternative technical solutions on the market, much emphasis when choosing strengthening solutions of connections is still placed on their capacity to enhance the overall strength of the system, rather than improve its ductility or ability to dissipate energy. When connections between vertical elements, and between vertical and horizontal elements, as well as vaults and domes have sufficient capacity, vertical and horizontal loads are better distributed, out-of-plane mechanisms of damage are prevented, and, hence, failure of floors and roofs can be avoided, substantially reducing the probability of collapse and fatalities in an earthquake.

Historically, builders mastered the art of careful detailing of joints from a process of trial and error; today's engineers possess the necessary insight into physical and mechanical laws governing the dynamics of structures to control the process of structural upgrading at the design level. Thus, when connections, in existing buildings, lack adequate capacity, further elements can be added to the original structure to achieve the desired performance.

The review of modern techniques to enhance connections presented in the previous section highlights aspects specific to each applications as well as advantages and pitfalls typical of each system. A large majority of the discussed methods are applicable both at the local and global scale for repair and upgrade of single structural elements or of whole structures.

In respect to the past, strengthening systems for structural connections rely on a more accurate design, modern structural systems, and innovative and more durable materials, for example, stainless steel or titanium, which substituted iron in cross-ties, with considerable advantages

Seismic Strengthening Strategies for Heritage Structures, Table 2 Performance parameters typical of each strengthening technique

Typology of strengthening		Performance parameters
Ring beams		Flexural, tensile, and shear capacity of beam (kNm/kN)
		Capacity of fixings between ring beam and parent material (crushing or pryout of parent material, shearing off of fixings, shearing of parent material, etc.) (kN)
		Horizontal sliding shear capacity of the masonry underneath the level of the fixings of the ring beam into the parent material (—)
Wall plates		Flexural, tensile, and shear capacity of wall plates (kNm/kN)
		Capacity of fixings between wall plates and parent material (crushing or pryout of parent material, shearing off of fixings, shearing of parent material, etc.) (kN)
		Horizontal sliding shear capacity of the masonry underneath the level of the fixings of the ring beam into the parent material (—)
Steel connectors for floor/roof structures		Tensile capacity (kN) as minimum depending on
Anchoring with end plates		Combined tensile and bending strength of connector/tie (N/mm ²)
Anchoring without end plates and with grouting		Tensile capacity of fixings in timber elements (kN)
Nailing		Bond strength (for bonded systems) connector/binder (N/mm ²)
		Bond strength (for bonded systems) binder/parent material (N/mm ²)
		Tensile capacity of fixings (frictional or mechanical fixings) in parent material (kN)
		Tensile strength of parent material for cone pullout or punching shear (N/mm ²)
		Reduction of tensile capacity due to distance to edge (%)
		Reduction of tensile capacity due to distance between anchors, nails, and connectors (%)
		Compressive strength of parent material under action of end plate (N/mm ²)
		Flexural capacity of end plate (kN)
		Shear capacity (kN) as minimum depending on
		Shear strength of anchor (N/mm ²)
		Tensile strength of anchor for combined axial and bending load (N/mm ²)
		Bearing capacity of parent material (N/mm ²)
		Bearing capacity (for bonded system) of binder (N/mm ²)
		Shear capacity of fixings in timber elements (kN)
		Reduction of shear capacity due to distance to edge (%)
		Reduction of shear capacity due to distance between anchors (%)
Corners confinement	Column ties	Flexural, tensile, and shear capacity of columns (kNm/kN)
		Capacity of fixings between ring beam and parent material (crushing or pryout of parent material, shearing off of fixings, shearing of parent material, etc.) (kN)
	FRPs	Tensile capacity of FRPs (kN)
		Bond strength between FRP/parent material (N/mm ²) and the tensile and compressive capacity of the parent material (N/mm ²)
	Polymer mesh, PP mesh, steel mesh	Tensile capacity (kN) as minimum depending on
		Tensile strength of mesh (N/mm ²)
		Tensile strength of fixings (N/mm ²)
		Bond strength fixing/binder (N/mm ²)
		Bond strength binder/parent material (N/mm ²)
		Shear strength of parent material for cone pullout (N/mm ²)

Seismic Strengthening Strategies for Heritage Structures, Table 2 (continued)

Typology of strengthening		Performance parameters
Energy dissipation systems		Shear capacity (kN) as minimum depending on
		Shear strength of parent material at the interface strengthened/unstrengthened material
		Shear strength of fixings (N/mm^2)
		Bearing capacity of binder (N/mm^2)
		Bearing capacity of parent material (N/mm^2)
	Yielding anchor devices	Yielding load of device (kN)
		Allowable displacement after yielding (mm)
		Dissipated energy (kJ)
		Change in material properties during cyclic loading (e.g., hardening of metal, progressive crushing of parent material)
		Buckling of device
		Ultimate tensile capacity (kN) as minimum depending on
		Tensile strength of device (N/mm^2)
		Other checks same as traditional anchors
		Shear capacity (kN) as minimum depending on
		Shear strength of device (N/mm^2)
		Other checks same as traditional anchors
	Frictional anchor devices	Load for activation of frictional mechanism (kN)
		Ultimate tensile load of device (kN)
		Ultimate allowable displacement for sliding (mm)
		Dissipated energy (kJ)
		Change in material properties during cyclic loading (e.g., hardening of metal, deterioration of frictional surfaces, effect of thermal expansion, presence of debris on frictional surfaces, progressive crushing of parent material)
		Ultimate tensile capacity (kN) as minimum depending on
		Tensile capacity of device (kN)
		Other checks as traditional anchors
		Shear capacity (kN) as minimum depending on
		Checks as per traditional anchors
Energy dissipation system	RAG energy absorbers	Axial yielding load that leads to yielding of lead pins (kN)
		Allowable displacement after yielding (mm)
		Dissipated energy (kJ)
		Change in material properties during cyclic loading (e.g., hardening of metal, progressive crushing of parent material)
		Ultimate tensile capacity (kN) as minimum depending on
		Tensile strength of anchor (N/mm^2)
		Tensile strength of RAG device
		Tensile strength of parent material to punching failure (N/mm^2)
		Compressive strength of parent material under action of end plate (N/mm^2)
		Flexural capacity of end plate (kN)
	RETE energy absorbers	Yielding load of the lead wire (kN)
		Ultimate tensile load of device (kN)
		Allowable displacement after yielding (mm)
		Dissipated energy (kJ)
		Change in material properties during cyclic loading (e.g., hardening of metal, progressive crushing of parent material)

Seismic Strengthening Strategies for Heritage Structures, Table 2 (continued)

Typology of strengthening	Performance parameters
Shock Transmission Units (STUs) and viscous dampers	1st threshold – thermal deformations
	Allowable displacement (mm)
	Transmitted load for low-rate loading (kN)
	2nd threshold – low seismic excitation, connections expected to perform as pinned connections
	Allowable displacements (mm)
	Capacity (kN)
	Capacity of connectors between STUs and parent material at 1st threshold (kN)
	3rd threshold – higher seismic excitation, connections expected to have hysteretic response
	Allowable displacement (mm)
	Transmitted load (kN)
	Dissipated energy for hysteretic response (kJ)
Shape Memory Alloy Devices (SMADs)	1st threshold – thermal deformations
	Allowable displacement (mm)
	Transmitted load for low-rate loading (kN)
	2nd threshold – low seismic excitation, connections expected to perform as pinned connections
	Allowable displacements (mm)
	Capacity (kN)
	Capacity of connectors between STUs and parent material (e.g., pullout or tensile failure of fixings) (kN)
	3rd threshold – higher seismic excitation, connections expected to have hysteretic response
	Allowable displacement (mm)
	Transmitted load (kN)
	Dissipated energy for hysteretic response (kJ)
	ith threshold: same parameters as per 2nd and 3rd threshold repeated for the higher plateaus of Shape Memory Alloys

in terms of issues related to material deterioration (e.g., expansion due to corrosion, failures due to reduced resisting section).

Some of the techniques described have undergone revision after observation of their performance in the aftermath of major earthquakes proved that they are unsuited to certain applications. For instance, RC ring beams need to be especially well connected to bearing walls; otherwise, they tend to create shear failure in walls and collapse; furthermore, it has been shown that they are not a viable solution in case of multileaf masonry not well bonded.

Recent strengthening solutions are evolving to include issues of environmental compatibility

while remaining economically feasible, especially for vulnerable communities in developing countries.

The most important shift for future implementation is the increased awareness and technological research for economic solutions for ductility and energy dissipation-based devices, which can allow the improvement of performance of entire building stock in historic centers of earthquake-prone countries.

The performance of each system can be verified by determining the parameters and carrying out the checks summarized in Table 2. The parameters listed refer, when available, to dimensioning procedures prescribed by codes and

guidelines and otherwise from the available technical literature included in this review. Some of the systems in the table are not codified; therefore, the dimensioning procedure is not standardized or sometimes not reported for intellectual property reasons; in these cases parameters are suggested by the authors on the basis of their expertise and of the available information on the behavior of the various devices.

The major advantage of Table 2 is that parameters have been homogenized, using a common nomenclature, to facilitate the comparison of various techniques.

Introduction

Volcano tomography is a branch of geophysics oriented to studying the deep structures beneath volcanoes by means of seismic tomography. **Seismic tomography** is a method for reconstruction of continuous distribution of seismic parameters in 1D, 2D, 3D, or 4D (space and time) using the characteristics of seismic waves traveling between sources and receivers. Seismic parameters to be found in tomographic inversion are in most cases velocities of P and S seismic waves (P and S velocities). For volcanoes, one of the key parameters appears to be the V_p/V_s ratio which can be used to evaluate the content of fluids and melts. Besides the velocity distributions, seismic tomography may provide the information on the anisotropy of seismic parameters which helps studying regional stresses and space-oriented geological structures. In some tomography studies, the target parameter might be the attenuation of P or S waves which may also give important information on magma sources beneath volcanoes.

At all stages of the human history, understanding the mechanisms causing volcano eruptions was one of the most intriguing problems.

Until relatively recent time, scientists had only indirect ways to explore processes beneath volcanoes, mainly by making analogies with geological signatures of ancient magmatic systems. During the last decades, the advancement of geophysical methods made possible direct observations of deep structures beneath presently active volcanoes which give precious information about general mechanism of working the volcanic systems. Among all geophysical methods, seismic tomography is one of the most powerful and effective approaches to look at great depths below the volcanoes. Using powerful artificial and natural sources of seismic signal makes it possible getting the information from depths where the main magma sources are located.

Observation Schemes

The configurations and characteristics of observation systems in seismology depend on the properties and sizes of the target objects, as well as on the type of seismic sources. In case of volcano seismology, the parameters of the target volume depend on the type of volcanoes. For example, the subduction-related volcanoes usually have complex multilevel structures of feeding system which may cover the depths down to 100–200 km. In the case of the hot-spot volcanoes, the initial source of magmatism is related to mantle plumes which may propagate throughout the mantle; however, the magma reservoirs and the related seismicity are fairly shallow in this case (only the first kilometers of depth). When designing an experiment for tomography studies of volcanoes, one should clearly figure out the target properties and define the configuration of the network according to this. In reality, there are many limitations, such as insufficient amount of instruments and difficulties in access to some areas around a volcano that make impossible deploying an ideal network. In the following section, the major components of the observation systems are described, and some recommendations to optimize the designing of the seismic networks are given.

Seismic Sources

Sources used for seismic imaging of volcanoes can be divided in three categories: human-made sources, earthquakes, and ambient seismic noise. Fully controlled artificial sources are expected to provide the highest accuracy of tomographic images. At the same time, their implementation on volcanoes is very sophisticated and expensive. Another shortcoming of artificial sources is that they cannot be produced at depth. In regions with well-distributed volcanic or local tectonic seismicity, earthquakes may give a distribution of sources plausible for high-resolution seismic tomography. However, many volcanoes do not generate sustained seismicity. In this case, the recently developed methods based on correlations of ambient seismic noise become suitable for imaging volcanic edifices.

Human-Made Seismic Sources

Human-made seismic sources include explosions, vibrators, air-gun shots, and weight (or mass) drops and are usually called **active sources**. There are some onshore experiments which use chemical explosions of sufficiently large magnitude to generate seismic signal propagating to the distances of dozens kilometers and depths of a few kilometers. The problem of such explosions is that they are fairly expensive and thus their number is strongly limited. Furthermore, chemical explosions are not ecologically friendly and they are prohibited in most volcanic areas. In most cases, the surveys based on such sources are used for 2D profiling (Fig. 1c).

An alternative method of active-source onshore generation might be using vibrators which are more ecologically safe compared to explosions. However, for the purposes of volcano tomography, the vibrators should be sufficiently powerful and heavy to enable the required propagation of seismic rays. In reality, the transportation of powerful vibrators appears to be not possible in most volcanic areas; therefore, they are not widely used in practice.

In case if a volcano is located close to the seashore, it is possible to use underwater air guns as sources of seismic signal (Fig. 2a). The advantage is that air-gun shots are rather cheap

Seismic Tomography of Volcanoes, Fig. 1 Observation schemes used in volcano tomography. Blue triangles depict seismic stations; red dots are sources; black lines are seismic rays

and sufficiently powerful. They can be frequently generated along the ship cruise that gives a huge data base with a clear technology of processing. The problem is that these sources are limited by the shore line and not suitable for most volcanoes.

The major advantage of the active sources is that their parameters are known. The problem is that they are located close to the surface, and seismic signal propagate along the nearly horizontal ray paths. Another problem, which is

Seismic Tomography of Volcanoes,

Fig. 2 Schemes for active-source experiments using air-gun shots (**a**) and for ambient noise tomography (**b**). *Blue triangles* depict seismic stations; *red dots* are sources

a Active-source scheme (airgun shots)

b Scheme for ambient noise tomography

mostly actual for the air-gun shots, is that they generate very weak S waves which cannot be picked and used for tomography studies.

Earthquakes

Volcanic and tectonic earthquakes located in the volcanic area (including some events located outside the perimeter of the network) are regularly used as sources for seismic tomography of volcanoes (Fig. 1b). The major problem with earthquakes is that their location parameters (coordinates and origin times) are not exactly

known and must be determined simultaneously with velocity models. This leads to a coupled problem with significant trade-off between velocity and source parameters. However, an important advantage of natural sources compared to the artificial sources is that they are located at some depths which allow illuminating the target object from below at different directions. For many cases, the amount of earthquakes is much larger than that of the artificial explosions. In addition, earthquakes in most cases produce clear P and S waves which can be used for exploring P and

S velocities. In turn, both P and S velocities give much more constraints on the petrophysical state of rocks below volcanoes than just a single P model.

Ambient Seismic Noise

Ambient seismic noise is the permanent motion of the Earth surface that is not related to earthquakes or specific controlled sources (see also “► [Seismic Noise](#)”). When averaged over long time series, this wavefield can be approximately considered as produced by randomly and homogeneously distributed sources (Fig. 2b). Cross-correlation between records of such random wavefields at two stations yields the impulsive response of the media (Green’s function) between these two points (e.g., Gouédard et al. 2008). In the present form, every recorder can be converted into a “virtual” source recorded at all other recorders resulting in $N(N-1)/2$ source-receiver pairs for a network of N stations, as shown in Fig. 2b. Shortcomings of noise-based approach are (1) dependence on noise sources distribution that in many cases is not perfectly homogeneous possibly preventing successful reconstruction of impulsive responses for a part of station pairs; (2) need of long continuous records (months or years); and (3) the fact that reconstructed virtual sources are located at the surface and are dominated by surface waves.

Receivers

Networks for active and passive surveys on volcanoes use generally the same instruments as for similar seismological studies in other regions. Tomography inversion needs numerous stations in a network (more than ten) which are usually deployed temporarily. Such networks consist of portable seismic stations which are composed of three major components: sensor, recorder, and power supply. In some cases, there is also a device for telemetric transition of signal.

Seismic sensor is a kind of “microphone” which converts the ground movements into electric signal. Modern sensors which are used for volcano surveys are three-component broadband instruments which allow recording oscillations of more than 30–40 s period (see also “► [Principles](#)

of Broadband Seismometry”). It should be noted that for the body-wave tomography based on local seismicity such broad frequency capacity is not really required: the signal from local earthquakes is clearly seen at frequencies of more than 1 Hz.

Seismic recorder is a tool which digitizes the analogue electrical signal coming from the sensor and records it onto a flash or another kind of memory. In each recorder, there should be also a GPS receiver which synchronizes the absolute time. In some cases, sensors and recorders are combined in one unit.

All recorders and most broadband sensors consume the electric power, and an important part of the seismic station is **power supply**. It can include chemical rechargeable or single-used batteries, solar panels, or wind generators. Using each type of power source is determined by the conditions of real experiments. For example, in Kamchatkan volcanoes, solar panels cannot be used due to large amount of snow during the most part of the year. Furthermore, there is a risk of destruction of any part located outside the ground by wild animals or vandals. In this case, an only possibility to conserve the station is to place the station deep into the ground together with batteries.

Some Hints on the Network Design

Design of seismological networks for performing tomography studies has some particular features. Here some hints which should be taken into account while deploying seismic networks are given.

- In case of using refracted rays from active (artificial) sources, when both sources and receivers are located near the surface, a typical depth of seismic ray propagation is 1/10–1/15 of the source-receiver distance (Fig. 1c). Thus, to study the depths of ~10 km beneath the volcano, the sources and receivers should be located in the opposite sides of the volcano at distances of 50–70 km.
- The spacing between stations normally has the same order as the minimum size of resolved anomalies in the tomographic inversion.

Further decrease or increase of the resolution depends on the distribution of events. If there are a very few events, densification of the network would hardly bring to the resolution increase. In contrary, in case of a large amount of sources evenly distributed throughout the study area, the resolved patterns can be smaller than the station spacing.

- For passive sources (local earthquakes), the depth of seismic model resolved from tomographic inversion cannot be larger than the maximum depths of sources.
- For uncontrolled sources (earthquakes), a critical parameter for tomography is a number of picks per events. If this number is equal to 4, one can theoretically locate the sources but cannot get any information about the velocity model. In practice, the data are noisy, and to get a stable location of source, more than four picks are required. The information on the velocity structure can be extracted only if the number of picks is more than 10. The higher this value is, the more velocity parameters can be retrieved and the higher resolution model will be obtained.
- Using out-of-network events (within reasonable limits) can appear to be useful for tomography as was shown by Koulakov (2009b). Although the location accuracy for such events is fairly low, they improve the ray coverage and help in increasing the spatial resolution beneath the network area.
- In all cases, prior the deployment of the network, it is useful to simulate a series of synthetic models with possible configurations of network, sources, and target objects that are expected in the real case. This can help to optimize the distribution of seismic stations in the real experiment.

Seismic Tomography Methods Based on Body Waves

Basic Principle of Body-Wave Seismic Tomography

In the ray-based approach which is used in most body-wave tomography algorithms, seismic

waves are produced by point sources. Along this way, seismic rays accumulate the information on the inner structure of the Earth. The purpose of seismic tomography is to decipher this information and to reconstruct the structure inside the Earth. Most simple and most popular way for many practical applications, including volcano tomography, is the kinematic approach based on using travel times of seismic rays. Travel times of seismic rays can be represented as an integral along the ray paths

$$T = \int_{\gamma} \frac{dS}{V(x, y, z)} \quad (1)$$

where γ is the ray path and V is seismic velocity. Here, an infinite frequency of the wave is presumed which allows presenting the ray as a curved line. Actually, this is often not true in seismology where the wavelengths are in some cases compatible with the size of the target objects. For these cases, there are methods of finite-frequency tomography which are based on “fat” rays representing a banana-shaped area having a rather complex sensitivity patterns (e.g., Husen and Kissling 2001). Although there are some successful applications of this method in global or in teleseismic tomography (Montelli et al. 2004), it was not yet widely implemented for volcano tomography. Up to today, most of the practical applications for studying the volcanoes are based on the ray-based kinematic approach.

In general, the velocity field in Eq. 1 is a function which is represented by infinite number of mathematical points. In practice, to solve the inverse problem, i.e., to derive velocity distribution based on given travel times, the velocity field should be parameterized with a finite number of parameters. There are different methods of parameterization, such as using regular or irregular cells, nodes with linear interpolation, harmonic functions with unknown coefficients, etc.

Another problem of solving the inverse problem based on the representation in Eq. 1 is that this problem is nonlinear. It means that one should find the velocity distribution based on the ray paths which are strongly affected by the

unknown velocity distribution. The direct solution of this nonlinear problem is almost never used for practical applications. Actually, in most cases, this problem is reduced to the linear representation. It is assumed that the unknown velocity distribution is close to the given reference model, and in this case, the problem in Eq. 1 is reduced to the linear integral

$$\Delta t = - \int_{\gamma_0} \frac{\Delta v dS}{V_0^2(x, y, z)} \quad (2)$$

where Δv is unknown velocity anomalies, Δt is time residuals, V_0^2 is velocity in the reference model, and γ_0 is the ray path in the given reference model. Then, the continuous representation in Eq. 2 can be reduced into the discrete system of linear equations:

$$\Delta t_i = \sum_j A_{ij} \Delta v_j \quad (3)$$

where Δv is the unknown value of j th velocity parameter and A_{ij} is the first-derivative matrix which represents an effect of a unit velocity change of j th parameter on travel time i th ray. In the case of cell parameterization, each element of this matrix is just the length of j th ray in i th cell. In the case of uncontrolled sources, this matrix also includes the elements for relocation of sources (four parameters, dx , dy , dz , and dt , for each source). In practical tomography studies, where this matrix may appear to be very large, the system in Eq. 3 is solved using the iterative LSQR algorithm (Paige and Saunders 1982) which proceeds only nonzero elements in the matrix and performs the calculations line by line without keeping the entire matrix in the memory. The direct solving of the system as it stands in Eq. 3 normally fails because of strong instability of the solution due to noise in the data. To avoid this problem, the inversion should be regularized using some additional terms. The most popular way of regularization is the amplitude damping which is realized by adding a diagonal matrix block with zero data vector. Another way is damping a gradient between all pairs of

neighboring parameters (nodes or cells) that allows controlling the smoothness of the solution.

The quality of the solution and optimal values of the inversion parameters are estimated based on synthetic modeling which should simulate the conditions of a real experiment as close as possible. The synthetic travel times are computed in an artificial model and perturbed by a realistic noise. Then, the model parameters are “forgotten,” and the reconstruction procedure is performed identically as in the case of observed data processing. This step is especially important for the volcano tomography where the distributions of sources and events are often far from optimal.

There are different seismic tomography schemes which are used for different purposes in geosciences. Many of them are used for studying the volcano feeding systems on scales from the entire mantle (thousands kilometers) to the uppermost layers (hundreds meters) (e.g., Koulakov 2013). Here, only some examples of tomography studies on scales from first to dozens kilometers are given. They provide the information about magma sources in the crust and uppermost mantle that are directly responsible for eruptions of active volcanoes.

Teleseismic Tomography

Seismic tomography is a relatively young method which started actively developed from the late seventies after the pioneer work by Aki et al. (1977). The method proposed in this study is called **teleseismic tomography**, and it uses the relative time delays from distant (teleseismic) earthquakes recorded by seismic stations located in the study area (Fig. 1a). There were several attempts of using this method for studying the volcanoes. For example, Ellsworth and Koyanagi (1977) have implemented the teleseismic scheme for studying the crustal structure beneath Kilauea volcano in Hawaii. Three years later, Sharp et al. (1980) have published the tomographic model for Mt. Etna. Among later studies, one can mention the work by Stauber et al. (1988) who presented tomographic models of Newberry Volcano, Oregon, based on teleseismic delays.

It should be noted that during the last decades, the teleseismic tomography is almost not used

any more for studies of crustal structures beneath volcanoes because of several reasons. The first problem is that nearly vertical seismic rays in the study area cause poor vertical resolution which leads to strong vertical smearing of the retrieved anomalies. Another problem, which seems to be more serious, is related to the fact that the teleseismic waves are usually of low frequency (around 1 Hz and lower). Thus, the large wavelengths strongly limit the resolution capacity of this method. Theoretically, it cannot provide robust images of anomalies smaller than 8–15 km. Magma reservoirs are usually expected to be smaller in size, and thus, they are hardly resolvable by teleseismic tomography.

Local Earthquake Tomography

Another method, which is called **local earthquake tomography (LET)**, uses the data of arrival times of P and S waves from earthquakes located within the study area or slightly outside (Fig. 1b). Because of using the uncontrolled sources, the solution in this case is reduced to the coupled problem of simultaneous determination of source parameters and velocity models. Active volcanoes usually produce a lot of seismicity related to processes in magmatic reservoirs and tectonic displacements in the crust. Therefore, deploying stations for the LET experiment is much cheaper than organizing active-source works with the use of explosions or air-gun shots. Furthermore, the earthquakes in passive source schemes are distributed at some depths that enable much more favorable observation system than in the case of active-source studies. In addition, seismic records from earthquakes usually provide the data on P and S waves that allows getting more information on petrophysical state of rocks in volcanoes than just a single P-velocity model which is usually resulted from the active-source studies. The problem of LET studies is an uncontrolled distribution of sources which is not always optimal to get optimal ray coverage in the target areas. An important difficulty of LET is the uncertainty of the source locations and the trade-off between source and velocity parameters. Another technical problem of LET is the necessity of fairly long

deployment of a large number of seismic stations (for more than several months) which is required to accumulate sufficient information on the seismicity in the volcano area. This needs solving some logistical issues related to providing power supply and hiding the equipment.

The first LET algorithm was developed and implemented to real seismological data by Thurber (1983). One year later, the same algorithm was used for studying the crustal structure beneath Kilauea volcano (Thurber 1984). Among the later studies based on this approach, one can single out the studies of Hengill-Grensdalur volcanic complex in Iceland (Foulger and Toomey 1989) and of Mount St. Helens (Lees 1992). There are more than ten different LET studies of Mt. Etna which appears to be one of the best studied volcanoes in the world (e.g., Villasegnor et al. 1998; Chiarabba et al. 2000; Patane et al. 2006). Note that the work by Patane et al. (2006) was a pioneer study presenting the 4D tomography model which revealed temporal variations of seismic structure beneath the volcano having possible relations to the eruption activity (see also “► [Seismic Monitoring of Volcanoes](#)”). During the last decades, the LET methods have become the most popular for studying crustal structure beneath volcanoes. Nowadays, there are dozens of successful studies of volcanoes in different parts of the world. In the final part of this paper, two examples of recent studies of Mt. Spurr in Alaska (Koulakov et al. 2013a) and of Klyuchevskoy volcano group in Kamchatka (Koulakov et al. 2011, 2013b) will be presented. Both of these studies were performed using the LET code LOTOS (Koulakov 2009a).

Studies with Human-Made Sources

Human-made sources or active sources are used in many seismic studies of volcanoes. The first experiments of three-dimensional active-source investigations of volcanoes were made in two relict calderas located in the Cascade Range, western USA. One of them is the potentially active Newberry shield volcano with the caldera of ~8 km diameter. In the active seismic experiment, Achaer et al. (1988) used three chemical explosions and a dense receiver network covering the caldera. They obtained a rather clear

low-velocity anomaly at about 3 km depth which was interpreted as a magma chamber. Another study was made in the same year in the Medicine Lake Caldera by Evans and Zucca (1988). They deployed 120 seismometers and made eight chemical explosions which were recorded by all stations. The tomography inversion of travel time data revealed a low-velocity pattern beneath the caldera which was also interpreted as a magma source.

Performing 3D experiments using onshore explosions appeared too expensive and not providing sufficient spatial resolution with the available number of explosions. Therefore, many onshore experiments were mostly organized along one or several profiles (Fig. 1c). For example, Zollo et al. (1996) used four chemical explosions on a profile passing through the summit of the Vesuvius volcano (Italy). Their P-velocity model reveals a rather clear high-velocity anomaly beneath the volcano. A similar experiment, but with five explosions on two crossing profiles, was performed by Aoki et al. (2009) for the Asama volcano in Japan. Similarly, as in the previous case, they found a clear high-velocity body beneath the volcano.

It should be noted that logistically the experiments based on chemical explosions are very difficult. Because of high expenses, the number of shots is strictly limited that makes it problematic to illuminate the target objects from different directions. Furthermore, the 2D approximations are often too rough for the volcanic areas where the expected structures are strongly 3D. In addition, the explosion type sources are not ecologically safe, and in most volcanic areas, they are prohibited now.

Good solutions for areas which are close to the seashore are the underwater air-gun shots which can be used to generate high-quality and sufficiently powerful seismic signal and can surround the target area (Fig. 2a). Nowadays, this scheme is widely used in experiments in many volcanic areas. Among many different studies, three examples are selected here:

- A very interesting site for seismic investigations is the volcanic Deception Island in

Antarctic which was studied by Zandomenighi et al. (2009). This island has a circular shape and is suitable for performing air-gun shots inside and outside the circle. Using onshore and offshore seismometers made this observation system suitable for high-resolution tomography studies. The inversion of travel time data revealed the seismic structures down to ~ 2 km which appeared to be linked with the main geological structures. The circular rim of the caldera is associated with high-velocity lineaments. Inside the caldera, a low-velocity anomaly is observed.

- A network with onshore and offshore stations and 4,414 air-gun shots were used by Paulato et al. (2010) to build a tomographic model beneath Montserrat Island in Lesser Antilles. They found that the location of the Island is associated with high P velocity. Especially sharp positive anomaly is located beneath the Soufriere volcano.
- The high-resolution 3D structure beneath the Tenerife Island was studied by Garcia-Yeguas et al. (2012) based on a large amount of air-gun shots and fairly dense onshore seismic network consisting of 140 stations. The main volcanic structure of the Las Cañadas-Teide-Pico Viejo Complex (CTPVC) is characterized by a high P-wave velocity body, similar to many other stratovolcanoes. Furthermore, reduced P-wave velocities are found in a small confined region in CTPVC and are more likely related to hydrothermal alteration, as indicated by the existence of fumaroles.

Imaging and Monitoring of Volcanoes Based on Ambient Seismic Noise

General Principle, Data Processing, and Inversion Approaches

New methods for probing the Earth's interior using noise records only emerged during the last decade (e.g., Campillo et al. 2011). Origin of seismic noise strongly depends on the considered spectral range (see also "► Seismic Noise"). At high frequencies (>1 Hz), the noise is strongly dominated by local sources that are often related

to strong winds or the anthropogenic activity. Seismic noise at intermediate periods (between 1 and 20 s) that is most often used for studies of volcanoes is dominated by natural sources. In particular, the two main picks in the seismic noise spectra in this so-called microseismic band (1–20 s) are related to forcing from oceanic gravity waves. The interaction between these oceanic waves and the solid Earth is governed by a complex nonlinear mechanism (Longuet-Higgins 1950), and the noise excitation depends on many factors such as the intensity of the oceanic waves but also the intensity of their interferences as well as the seafloor topography. Overall, the generation of seismic noise is expected to be strongly modulated by strong oceanic storms and, therefore, to have a clear seasonal and nonrandom pattern. However, when averaged over long time series, distribution of sources of microseismic noise can be approximated as random and homogeneous. In this case, cross-correlation of noise records between two stations yields the impulsive response (Green's function) between these two points (e.g., Gou  ard et al. 2008). In the case of a uniform spatial distribution of noise sources, the cross-correlation of noise records converges to the complete Green's function of the medium, including all reflection, scattering, and propagation modes. However, in the case of the Earth, most of ambient seismic noise is generated by atmospheric and oceanic forcing at the surface. Therefore, the surface-wave part of the Green's function is most easily extracted from the noise cross-correlations.

Seismic surface waves, in contrast with body waves, are waves that propagate in a waveguide near the Earth's surface. There are two types of **surface waves**: **Rayleigh** (vertically polarized waves) and **Love** (horizontally polarized waves transverse to the direction of motion). Their depth sensitivity depends on frequency, with a fair approximation being about a third of a wavelength. As a result, the surface waves are strongly dispersive with longer periods (wavelengths) propagating faster than shorter periods because of the general increase of seismic speed with depth in the Earth.

Using surface waves extracted from correlations of seismic noise for imaging of the Earth's interior is called **ambient noise surface-wave tomography**. This approach generally consists of three steps (e.g., Ritzwoller et al. 2011). First, noise cross-correlations between every pair of stations in the array are computed, and interstation phase or group travel times as a function of period are measured from the resulting waveforms. Second, two-dimensional maps of the speed of Rayleigh or Love waves as a function of frequency are produced. At the last step, these maps are inverted for a 3D distribution of shear speeds.

Applications of Ambient Noise Seismic Tomography (ANST) to Studies of Volcanoes

After recent emergence of the ambient noise surface-wave tomography (e.g., Shapiro et al. 2005), it became clear that this method might be very useful for studying structures within volcanoes because of its relatively low cost (especially comparing with active-source studies) and because of good coverage of the shallow part of edifices compared with earthquake-based body-wave imaging. First "volcanic" application of ANST was performed at Piton de la Fournaise located at La R  union Island (Brennguier et al. 2007). This hot-spot volcano is very active with on average more than one eruption per year during the past two centuries. The noise-based tomography was based on correlations of 18 months of records by 21 short-period vertical-component stations of the permanent volcano monitoring network. Rayleigh wave group velocities could be measured between 2 and 5 s of period. Inversion of these dispersion curves resulted in a shear velocity model extending between the surface and the depth of 1 km below sea level (while average elevation of the volcano is ~ 2 km). The main result of this study was imaging of an intrusive high-velocity body below the main crater moving westward from the surface to 1 km below sea level. This body is located above the shallow magma reservoir and coincides with the region through which the magma ascends during the summit eruptions.

Following the pioneering study of Brennguier et al. (2007), the ANST was applied to image

subduction zone volcanoes: Okmok in Aleutian Islands (Masterlark et al. 2010), Lake Toba in Sumatra (Stankiewicz et al. 2010), and Asama in Japan (Nagaoka et al. 2012). The first study used 12 stations from a permanent monitoring network, and the second study used 40 stations from a temporary deployment, while the third study used 81 sensors combined from permanent and temporary networks. In all these studies, the authors reported very similar results: imaging of low-velocity anomalies corresponding to magma reservoirs at depths below 4 km.

Noise-Based Volcano Monitoring

One of the advantages of using continuous seismic noise records to characterize the earth materials is that a measurement can easily be repeated (see also “► [Seismic Monitoring of Volcanoes](#)”). First application of this idea to volcano monitoring was done by Sens-Schönfelder and Wegler (2006) who used the repetitive waveforms of seismic noise cross-correlations to track changes in the subsurface material properties on mount Merapi in Indonesia during 2 years. This study was based on high-frequency (>1 Hz) waves and mainly revealed seasonal variations caused by changes of hydrological conditions in a very shallow layer. Brenguier et al. (2008) used noise cross-correlations at intermediate periods (between 1 and 10 s) to detect decreases in seismic velocity a few weeks before eruptions that suggests preeruptive inflation of the volcanic edifice of the Piton de la Fournaise. A comprehensive review of recent advancements in the noise-based volcano monitoring is provided by Brenguier et al. (2011) (see also “► [Tracking Changes in Volcanic Systems with Seismic Interferometry](#)”).

Current Limitations and Prospective

Application of seismic noise cross-correlation methods for studies of volcanoes is a rapidly growing field. However, these methods have some important limitations that are mainly related to the properties of the seismic noise recorded at the Earth surface. So far, the basic theoretical foundation of the cross-correlation method assumes a random and homogeneous

distribution of the wavefield sources, while properties of a real seismic noise may deviate from this simplified model. This implies that applications of the noise-based imaging or monitoring should be accompanied by studies of properties of recorded seismic noise to characterize the degree of its spatial and temporal inhomogeneity and to determine the minimal time required for good convergence of noise cross-correlations. Development of advanced methods for the preprocessing of the noise time series in order to improve the quality of the extracted signals and to decrease the convergence time is a very active research area.

Up to date, the noise-based seismic tomography was based on surface waves that are most easily extracted from noise cross-correlations but have a limited resolution in deep layers. Most recent results demonstrate that, when working with large and dense arrays of seismometers, it is possible to indentify body waves in correlation waveforms and to measure their travel times (e.g., Boué et al. 2013; Lin et al. 2013). This gives a hope that noise-based body-wave tomography of volcanoes could be developed in the future.

Examples of Tomography Studies of Volcanoes

Tomography of Mt. Spurr

Mount Spurr is an active predominantly andesitic volcano in Alaska located at the northeastern end of the Aleutian arc. Before a single eruption in 1953, it was considered as a dormant volcano. In 1992, a series of three explosive eruptive events occurred on June 27, August 18, and September 16–17 in a small composite cone forming the Crater Peak on the south flank of Mount Spurr. The structure beneath Mt. Spurr in a period of time nearly corresponding to this eruption was studied by Power et al. (1998) using the data collected from 1991 to 1993 by 7–11 seismic stations of the Alaska Volcano Observatory (AVO).

The most recent episode of Mt. Spurr unrest occurred in 2004–2006 which accompanied with

strong seismicity and fumarolic activity. However, this episode did not result at any magma eruption, and thus, it was called as “lost eruption.” For 1 month in June 2005 corresponding to the middle stage of this unrest, the AVO deployed a fairly dense seismic network consisting of 26 broadband three-component stations which operated in addition to 11 short-period stations of the permanent network. During this period, 512 crustal earthquakes were located in the area of Mt. Spurr using P and S picks recorded by portable and permanent stations. The final catalog contained 5,960 P- and 4,973 S-wave arrival times with an average of 20 picks per event. These data were used to perform the tomographic inversion presented in Koulakov et al. (2013a).

The result of tomographic inversion including the 3D distributions of P and S velocities, V_p/V_s ratio, and accurate source locations is presented in Fig. 3. The horizontal section at 5 km depth demonstrates a prominent anomaly of high V_p/V_s ratio which reaches the value of 1.9 located beneath the northern rim of the volcano. This pattern coincides with the distribution of shallow seismicity. In the deeper section at 22 km depth, this anomaly is located at the same place, but it appears to be less intensive than another zone of high V_p/V_s ratio which is collocated with a cluster of deep crustal earthquakes. In vertical section, these two anomalies look like two fingers of high V_p/V_s ratio separated by 8 km of lateral distance. One of the two anomalies nearly reaches sea level beneath the northern border of the caldera, but is separated from the surface with a zone of low V_p/V_s ratio. The top of the second anomaly appears to be much deeper and may reach a depth of 20 km. The earthquakes that occurred during the 3-month span show distinct clusters near the tops of each of these fingers which support the active behavior of these structures. It is important that for both these finger-shaped anomalies, the high V_p/V_s correspond to higher P and lower S velocities.

The observed finger-like features are suggestive of pathways through the crust and possibly correspond to complexes of conduits that transport liquid volatiles and/or melts from the mantle.

The combination of high V_p and low V_s suggests the presence of liquid fluids and/or melts and the rock composition corresponding to the low crustal or even mantle levels. The existence of very low values of V_p/V_s above the NW anomaly might be an indicative for aggregate transition occurred between the top of the plume and the surface. It is important that the NW finger location generally coincides with the presence of fumaroles and active volatile flux during the most recent eruption in 2004–2005. It can be proposed that this liquid fluids brought by the NW conduit are transformed to gases at shallow depths which can escape to the surface without producing any stresses. This explains lack of any explosive activity in this location during the 2004–2005 unrest of Mt. Spurr (Fig. 3).

Another conduit located below the Crater Peak seems to be blocked at ~ 20 km depth. This fact is supported by the occurrence of deep seismicity just above this anomaly. In this blocked channel, the accumulation of high pressure is more probable which makes it more dangerous for a potential explosive eruption. Note that the explosive eruption of Mt. Spurr in the SE rim in 1992 occurred just above this anomaly.

Tomography of the Klyuchevskoy Volcano Group

The Klyuchevskoy volcano group is located in Kamchatka, in the far east of Russia. It includes 13 active and dormant volcanoes of various types and compositions located in a relatively small area of approximately 100×60 km. The main volcano of the group, Klyuchevskoy Sopka, has the elevation of $\sim 4,800$ m, and it is the highest volcano in continental Eurasia. Another volcano of the group, Bezymianny, located at approximately 10 km distance from the Klyuchevskoy volcano is an explosive-type andesitic volcano. One of the world's largest explosive eruptions in the twentieth century occurred here in 1957. The Tolbachik complex is situated in the southwestern part of the Klyuchevskoy group, and it consists of several shield and stratovolcanoes of predominantly basaltic compositions. Plosky Tolbachik, which is currently active, is a typical Hawaiian-type volcano with fissure eruptions and

Seismic Tomography of Volcanoes, Fig. 3 Distribution of the V_p/V_s ratio in two horizontal and one vertical section. Dotted line depicts the limits of the caldera rim. Triangles indicate the locations of stations. Yellow dots mark the source locations. Bottom-right plot represents

the interpretation of the results. Blue wavy arrows indicate hypothetical migration of fluids and their escape to the atmosphere in 2004–2006 unrest (Reproduced from Koulakov et al. 2013a, JRL)

calderas. The existence of so many different volcanoes located close to each other can most likely be explained by complex processes of fractioning, mixing, and melting in magmatic reservoirs located under the volcanic group at different depth levels.

During the last several decades, the volcano-related seismicity in the Klyuchevskoy group has been monitored by the Kamchatkan Branch of Geophysical Survey. After 1999, a network consisting of 17 digital telemetric stations was installed in the region of the Klyuchevskoy group. From 1999 to 2009, it provided the information on more than 80 thousand events and the corresponding half million of P and S arrival times. The tomographic inversions were performed based on selected yearly subsets. The temporal variations of seismic structure are especially interesting in the context of the volcanic activity during the considered time. In particular, in 2005, there were simultaneous eruptions of the Klyuchevskoy and Bezymianny volcanoes that give a possibility to explore the changes of the crust related to the volcanic activity at stages of preparation, activation, and relaxation (see also “[Seismic Monitoring of Volcanoes](#)”).

The results of tomographic inversion corresponding to the year 2004 just before the activation phase were presented in a separate study by Koulakov et al. (2011). Similar structures are observed in the precedent 2003 year (Koulakov 2013). The key feature of these models is a strong anomaly of a high V_p/V_s ratio, reaching values of 2.2, located below 25 km depth. Within this anomaly, the P velocity appears to be higher than average, whereas the S velocity is strongly low. This combination of seismic anomalies is a possible indicator for a mantle conduit beneath the Klyuchevskoy group with rocks brought from deep levels and high content of fluids and melts. It was proposed that this conduit is the original magma source that feeds all of the volcanoes in the Klyuchevskoy group.

The tomography result corresponding to 2004 reveals complex contrasted structures in the crust which can be associated with magma sources. The distributions of high values of V_p/V_s ratio

reveal at least two levels of magma sources in the crust: one is located at a depth of 10–12 km and another is just below the Klyuchevskoy volcano close to the surface. This may explain the diversity of the volcanic styles in the group. The distribution of earthquakes appears to link different levels of magma storage that may trace the paths of magma migration.

Time variations of seismic structure beneath the Klyuchevskoy group in a time period from 1999 to 2009 were studied by Koulakov et al. (2013b) and presented in Fig. 4. A common feature which is seen in all yearly windows is the anomaly with an extremely high V_p/V_s ratio located below 25 km depth, which was previously mentioned for the year 2004 and interpreted as a mantle conduit feeding all volcanoes of the group. For the crust, this study demonstrates considerable temporal changes of seismic structures. In particular, prior the 2005 eruptions of the Klyuchevskoy and Bezymianny volcanoes, the seismic structures in the crust look generally similar and contain two anomalies of high V_p/V_s ratio beneath the Klyuchevskoy volcano at a depth of 10–12 km and close to the surface. As mentioned above, these anomalies are interpreted as two levels of magma sources. In 2005, the average value of the V_p/V_s ratio increases, and it may be explained by a considerable increase of the fluid and melt content in the crust. In this year, a strong anomaly of high V_p/V_s ratio is observed beneath the Bezymianny volcano, and it appears to link the volcano with mantle sources. In other years, this anomaly was not observed. The shallow anomaly of high V_p/V_s anomaly, which was previously observed beneath the Klyuchevskoy volcano, disappears in 2005. The deeper anomaly at 10–12 km depth is still presented. In the years after the eruption, 2006 and 2007, the average V_p/V_s ratio lowers, and all the patterns at 10–12 km depth that were interpreted as intermediate magma sources in the crust are not observed anymore. Three years later, in 2008, a similar anomaly at the same location starts reappearing again.

The observed variations of the seismic properties are probably related to changes in the stress and deformation fields, migration of fluids, and

Seismic Tomography of Volcanoes, Fig. 4 Cross sections of V_p/V_s from tomographic inversions for each year from 2001 to 2008 for a profile passing through Klyuchevskoy (KLU) and Bezmianny (BEZ) volcanoes. In areas of high V_p/V_s ratios, yellow lines show contours of $V_p/V_s = 2.0, 2.1$, and 2.2 . Dots show earthquakes less than 0.5 km from the profile, and triangles mark the locations of the volcanoes near the profile. The eruptions of Klyuchevskoy and Bezmianny volcanoes in 2005 are highlighted. The main phases and structural elements, which are discussed in the text, are indicated (Reproduced from Koulakov 2013, JVGR)

aggregate transformations in the crust. The mantle conduit, which is visible as an anomaly of high V_p/V_s ratio below 25 km depth at all time periods, should have strong mechanical, thermal, and/or chemical influence upon the bottom of the crust and cause strong seismicity. These stresses lead to the origin of fractures and upward penetration of the fluids to the crust. Reaching intermediate levels, these fluids lead to melting of the overheated rocks. Due to decompression, some of the fluids are transformed to gases that increase the pressure and cause additional fractures. These avalanche-type processes finally lead to the eruptions. During the eruption, most of the fluids escape to the atmosphere, and it causes a decrease in the melt content in the intermediate magma sources in the post-eruption period. Several years later, a new portion of fluids comes from the mantle conduit, and melting of rocks in intermediate reservoirs starts again. An important conclusion that can be drawn from the 4D tomography study is that the magmatic sources appear to be dynamic systems with rapidly variable properties. According to this concept, the magma sources are composed of sponge-type materials with the capacity to change the proportion of the molten partition depending on the presence of fluids. Propagation of cracks and fluids may occur rather rapidly, and this may abruptly change the properties of the “sponge” material over a period of years or even months or weeks.

Summary

This paper presents an overview with the description of several seismic tomography schemes which are used for studying volcanoes. It describes several examples of practical works including two featured case studies of Mt. Spurr and Klyuchevskoy volcano group. It was demonstrated that seismic tomography gives rich material which allows better understanding of the behavior of magmatic systems. A variety of the tomographic solutions show that there is no uniform structure: each volcano has some particular features and appears to be unique.

During the last years, there appear more and more dense networks on different volcanoes of the world designed for passive and active experiments. There are also new algorithms actively developed during the last years, such as scattering tomography or full waveform inversion, which might appear very effective for studying volcanoes. This gives a hope that increasing amount of data and implementing new algorithms will lead in the nearest time to a real breakthrough in understanding the causes of volcanic activity.

Seismic Vulnerability Assessment: Lifelines

Kyriazis Pitilakis and Sotiris Argyroudis
Department of Civil Engineering, Aristotle
University, Thessaloniki, Greece

Synonyms

Fragility curves; Infrastructures; Seismic risk assessment; Transportation networks (railway, roadway, harbor, airports); Utilities (gas, oil, water, wastewater, energy supply)

Introduction

Main Features of Lifelines

Lifelines refer to the complex system and network assets of connected components, usually interacting with other components and systems, which are performing vital functions that are essential to sustain the life and the growth of a community, such as producing, transporting, and distributing goods or services. Their global value for the society and economy is permanently increased in our modern, technologically advanced, highly demanding, and fragile world.

They constitute by themselves a set of critical facilities for the proper and safe functioning of the societies. In case of a strong earthquake motion, their physical damages and the consequent disruption of the services they provide may contribute seriously to the global economic loss. At the same time, their repairation cost may be very high, reaching in several cases 10 % or 15 % of the initial construction cost of the whole system to which they belong.

The term *lifeline* is ambiguous. Lifelines may be distinguished in two major categories: (i) Utility systems including potable water, natural gas, oil, electric power distribution, wastewater, or communication systems and (ii) transportation systems comprising roadways, railways, airport, and port facilities. Sometimes the terms infrastructures or critical facilities are used instead, at least for some of them.

Compared to buildings, lifeline systems present three distinctive features: (a) spatial variability and topology and exposure to different geological and geotechnical hazards, (b) wide variety of component typologies and material used, and (c) specific functionality requirements, which make them highly hierarchical networks. For practical reasons they are generally categorized in links (e.g., pipelines, roads) and nodes (e.g., tanks, power substations). Moreover, for their vulnerability assessment, an important parameter is the presence of synergies between components within the same system (intra-dependencies) or between different systems (interdependencies). Due to these synergies, the physical damage of a component of a system interacting with another one may affect seriously the second system's performance and functionality. Therefore, it is essential to define the taxonomy of each interacting lifeline system that describes the individual components of each system and their role in the network as well as the way other systems affect its performance.

Due to their spatial extent, lifeline systems are exposed to variable seismic ground motions, often presenting important incoherency (shaking effects), and to geotechnical hazards expressed in terms of permanent ground deformations, resulted from fault crossing, landslides, and

liquefaction (e.g., lateral spreading, settlements, buoyancy effects). Various parameters may be used to describe and characterize the strong ground motion and the induced phenomena. The selection of appropriate parameter (i.e., intensity measure), which is efficiently correlated with the response and the expected damages of each exposed elements, depends on the technical and response characteristics of each element.

As an example, a motorway network presents the following features: It includes multiple elements at risk like bridges, overpasses, interchanges, tunnels, culverts, embankments, cuts, slopes, retaining walls, signage and markings, electrical systems, rest areas, and buildings (e.g., tolls, maintenance, traffic management). These structures are usually built with different design methods, construction techniques, and materials. The seismic design requirements, and therefore their vulnerability, depend on the type and the location of the structure, the seismicity, and the tectonic features of the area. In particular, roadways are crossing different geological and topographical conditions such as valleys, rivers, canals, gulfs, or mountainous regions. Obviously, the network components can be exposed to various seismic ground motions in terms of amplitude, frequency, or duration, as well as to different geotechnical hazards (subsidence, liquefaction, landslides, faults, etc.). In this context, the design of a long bridge crossing an active seismic fault is much more demanding than a single span bridge in the same area. On the other hand, nowadays, the design level (and subsequently the resistance to earthquakes) is higher than of 30 years ago, making old structures more vulnerable, introducing a new factor, the aging or time effects. Furthermore, the hierarchy (importance) of roads depends on their traffic capacity, i.e., highways and major arterials and secondary and local urban roads. The importance of the road segments, serving different part of the urban fabric, depends also on the land use and the density of the population. The functional role of roads is related to the specific served areas such as industrial or residential areas, hospital facilities, and transport hubs (e.g., airports and major harbors). Therefore, the importance of each

individual infrastructure and part of the network is variable and at the same time an essential factor in the seismic risk management. Finally, the synergies that are presented in a road network and can affect its overall functionality in case of earthquake include the supply of electric power for the signaling and lighting and the proximity to buildings and utility networks (e.g., water or gas pipes) that may induce the interruption of road traffic.

Experience from Past Earthquakes

Several devastating earthquakes occurred during the last century, causing extensive losses in terms of fatalities, injuries, damages, and disruptions. Knowledge, experience, and lessons learned from past earthquakes have significantly contributed to disaster risk reduction efforts across the globe.

The 1971 San Fernando earthquake in USA ($M_L 6.6$), an event that caused catastrophic damage to almost all types of lifelines, motivated the evolution of the lifeline earthquake engineering as well as many new efforts to better understand the causes of these failures and identify ways to mitigate future earthquake damage and disruption (e.g., the establishment of the Technical Council of Lifeline Earthquake Engineering/TCLEE, in ASCE). Other strong and damaging earthquakes that contributed to the progress of lifeline earthquake engineering are the 1978 Miyagiken-oki (Japan, $M_s 7.7$), the 1985 Michoacan (Mexico, $M_w 8.3$), the 1989 Loma Prieta (USA, $M_w 6.9$), the 1990 Luzon (the Philippines, $M_s 7.8$), the 1993 Kushiro-Okai (Japan, $M_w 7.6$), the 1993 Hokkaido-Nansei-Okai (Japan, $M_w 7.7$), the 1994 Northridge (USA, $M_w 6.7$), the 1995 Hyogoken-Nanbu (Kobe) (Japan, $M_w 6.8$), the 1999 Chi-Chi (Taiwan, $M_w 7.6$), the 1999 Kocaeli (Turkey, $M_w 7.4$), and the 2001 El Salvador ($M_w 7.6$) events. More recent earthquakes which caused serious damages and losses to utility systems and transportation infrastructures, even in developed countries, include the 2004 Niigata ken Chuetsu ($M_w 6.8$) and 2007 Niigata-Chuetsu Oki ($M_w 6.6$) earthquakes in Japan, the 2008 Wenchuan (China, $M_w 7.9$), the 2009 L'Aquila (Italy, $M_w 6.3$), the 2010 Maule

(Chile, M_w 8.8), and recently in 2011 the Christchurch (New Zealand, M_w 6.3) and the mega 2011 Tohoku (Japan, M_w 9.0) earthquake and the tsunami associated with this earthquake.

The experience from major earthquakes proved that most lifeline elements are vulnerable, and the mid- and long-term effects, mainly in terms of financial losses, may be very important. A typical example of long-term effects is the port of Kobe in Japan, one of the largest container cargo ports in the world, which suffered major damages, mostly due to liquefaction-induced phenomena, as a result of the 1995 M_w 6.8 Hyogoken–Nanbu earthquake. A year after almost all port infrastructures have been reconstructed, but it is remarkable that in 1998, 3 years after the disaster, cargo traffic remained at roughly half of pre-disaster levels. For the same earthquake, the direct repair cost for the Hanshin Expressway was \$4.6 billion (NCEER 1995), while the total cost was actually much higher if the \$3.4 million of daily income from tolls and the losses from business interruption and traffic delays was taken into account. In the 1994 M_w 6.7 Northridge earthquake, the repair cost for damaged bridges was evaluated at \$190 million, almost the 10 % of the total cost of the whole transportation system (\$1.8 billion, Basöz and Kiremidjian 1998).

Interactions between systems may have a significant impact exceeding direct consequences. Loss of power or communication can severely impact the emergency response, especially when the disruptions concern critical facilities, such as hospitals, command centers, etc. Loss of power may have severe indirect effects due to the synergies between the lifelines and the dependence of all networks on the power supply system. In 1989 M_w 6.9 Loma Prieta earthquake, the damages that occurred in the water network greatly affected the fire-fighting capacity in the area of San Francisco, Oakland, and Berkeley. Representative cases of interactions have been also reported after the 1994 M_w 6.7 Northridge and 1995 M_w 6.8 Hyogoken–Nanbu earthquakes, when the reparation of the water and gas networks have been delayed due to traffic congestion, street blocking, damaged buildings, and

water that flowed into gas pipelines. A large area was also burned down in Kobe due to the disruption and the inefficiency of the fire-fighting network. Considering that modern societies and built environment are relying on the good performance of their interconnected infrastructures, it is clear that an efficient rescue policy and an optimum recovery strategy after a strong earthquake require the evaluation of the interactions between different lifeline systems.

In addition to ground shaking, ground failures (i.e., landslides, liquefaction, later spreading, fault ruptures), if they occur, may produce even more severe damages and losses to lifelines and infrastructures. As an example, the 2008 M_w 7.9 Wenchuan earthquake in China triggered more than 15,000 landslides of various types within an area of 50,000 km² and causing more than 20,000 fatalities representing one-quarter of the total fatalities. The landslides produced extensive damage to housing settlements, irrigation channels, highways, bridges, and other infrastructures. The city of Wenchuan and many other towns were isolated from the rest of the country, and the rescue and relief efforts were greatly affected due to blocking and damages in road network (Tang et al. 2011). During the 2010 M_w 7.1 followed by the 2011 M_w 6.3 Christchurch earthquake sequences in New Zealand, the ground and slope failures, mainly due to liquefaction, produced extensive damages to the water, electricity, and road networks rendering many of them inoperable (O'Rourke et al. 2012). On the contrary the gas system performed rather well. A large number of slope failures, landslides, and rock falls occurred during the 2004 M_w 6.8 Niigata ken Chuetsu earthquake on steep natural slopes and artificial cuts in the area, resulting in major damage to road and railway infrastructures (cuts, embankments, pavements, tunnels, abutments, retaining walls), as well as to other lifeline components (water pipes, electric power poles). Similar damages and disruptions, related to geotechnical failures, were recorded after the subsequent 2007 M_w 6.6 Niigata-Chuetsu Oki earthquake in Japan and in several recent events in Europe (e.g., 2003 M_w 6.4 Lefkas earthquake in Greece, the 2009

Seismic Vulnerability Assessment: Lifelines,

Fig. 1 Damages to road, telecommunication, and gas system in 1994 Northridge ($M_w 6.7$) earthquake (Photo Credit: US Geological Survey)

Seismic Vulnerability Assessment: Lifelines,

Fig. 2 Damaged equipment in Adapazari substation in 1999 Kocaeli ($M_w 7.4$) earthquake (Photo Credit: Kandilli Observatory and Earthquake Research Institute/KOERI)

$M_w 6.3$ L'Aquila earthquake in Italy, the 1999 $M_w 7.4$ Kocaeli earthquake in Turkey) and worldwide. In Figs. 1, 2, 3, 4, 5, 6, 7, and 8, some representative damages for utility and transportation networks are shown.

Several utility systems and networks are now outdated and lack proper seismic design and protection. For example, there are parts of the water and wastewater systems in several cities built more than a century ago. Hence, their material properties and strength are seriously affected from aging effects and are consequently more vulnerable and exposed to earthquake risk. Currently, most of urban infrastructures are not designed to sustain severe seismic hazard and complex systemic threats, and it is difficult to anticipate what may be the complex socio-economic losses due to potential strong earthquakes.

The poor performance of elements at risk in a network is likely to make the whole system much more vulnerable and susceptible to strong earthquakes.

Finally, the short- and long-term economic impact due to earthquake damages of lifelines can be significant. In a recent study by CATDAT (Daniell and Vervaeck 2013), the disaggregation of direct economic losses of 61 selected major earthquakes from 1900 to 2012 showed that around 30 % of the direct losses came from infrastructure losses in transport, communications, pipelines, energy supply systems, etc.

Lifeline Earthquake Engineering Research

In the last two decades, several important projects and research efforts related to the vulnerability and risk assessment of different lifelines at

Seismic Vulnerability Assessment: Lifelines, Fig. 3 Lateral deformation of train tracks at the Arahama station due to surface waves in 2007 Niigata-Chuetsu Oki ($M_w6.6$) earthquake (Photo Credit: US Geological Survey)

regional or urban scale have been undertaken. They resulted in the development of relevant methods and guidelines. A short reference to the most important contributions is following.

United States

In 1992, the Multidisciplinary Center for Earthquake Engineering Research (MCEER) initiated the Highway Project, funded by the Federal Highway Administration (FHWA). The project uniquely examined the impact of earthquakes on the highway system as an integrated network, rather than a collection of individual road segments, bridges, embankments, tunnels, etc. The purpose of the project was to ensure the usability of highways following earthquakes, by improving performance of all interconnected components. Overall goals were to deepen the understanding of the seismic hazard impact to highways and to improve and develop analysis

Seismic Vulnerability Assessment: Lifelines, Fig. 4 Damages to road embankments in 2007 Niigata-Chuetsu Oki ($M_w6.6$) earthquake (Photo Credit: US Geological Survey)

methods, screening procedures and additional tools, retrofit technologies, design criteria, and other approaches to reduce seismic vulnerability of existing and future highway infrastructure. REDARS (Risks due to Earthquake DAMAGE to Roadway Systems) is a public-domain software package developed under this MCEER project that accounts for how earthquake damage affects post-event traffic flows and travel times and estimates losses from these travel-time and traffic-flow impacts (<http://mceer.buffalo.edu/research/redars/>).

In 1996, the PEER Lifelines Program (<http://peer.berkeley.edu/lifelines>) was initiated, under the coordination of the Pacific Earthquake Engineering Research Center, funded by the California Department of Transportation and the Pacific Gas and Electric Company. The aim was to improve the seismic safety and reliability of lifeline systems with particular focus on the characterization of ground motions, local soil and site response, and the performance of bridge structures and electric substation equipment.

In 1997, the Federal Emergency Management Agency (FEMA) released the first edition of HAZUS methodology and software that

estimates potential building and infrastructure losses from earthquakes, built using GIS technology. The current version is HAZUS-MH V2.0, including also losses from floods and hurricanes.

It was released in 2004 (www.fema.gov/hazus). HAZUS-MH loss estimates reflect the state-of-the-art scientific and engineering knowledge and can be used to inform decision makers at all

Seismic Vulnerability Assessment: Lifelines, Fig. 8 Failure of port infrastructures in 1995 ($M_w 6.8$) Hyogoken–Nanbu earthquake (Photo by K. Pitilakis)

levels of government by providing a reasonable basis for developing mitigation, emergency preparedness, response, and recovery plans and policies. The main merit of the HAZUS platform is that it provided for the first time an unparalleled set of fragility models for all the main components and systems of the built environment. However, it must be recognized that many of these models have been derived solely on expert judgment and the level of knowledge at that time. One effect of the sheer size of the HAZUS framework and its set of tools is that it established itself very soon as the reference for all studies in the sector worldwide.

In 1998, FEMA and the American Society of Civil Engineers entered into a cooperative agreement to establish the American Lifelines Alliance (ALA). ALA's objectives were to facilitate the creation, adoption, and implementation of design and retrofit guidelines and other national consensus documents to improve the performance of utility and transportation systems (electric power, telecommunication, water, wastewater, oil, natural gas, rail, and shipping ports) in natural hazard events, including earthquakes. ALA has not attempted to focus efforts on all lifeline systems and components but has instead chosen to place priority on specific topics relevant to selected lifeline systems where a need for improved hazard mitigation practices is identified. The primary function was to bridge the gap between hazard mitigation practices for buildings and lifeline systems; therefore a close collaboration with lifeline

stakeholders, owners/operators, and recognizing regulatory bodies was established to facilitate use of developed guidelines (<http://www.americanlifelinesalliance.com/>).

ERGO (the new name for the Multi-Hazard Assessment, Response, and Planning software previously known as mHARP and MAEvis) started somewhat later than HAZUS and was the product of the research efforts carried out at the Mid-America Earthquake Center in collaboration with the National Center for Supercomputing Applications (NCSA). It is an open-source software and incorporates many of the design concepts and capabilities motivated by NCSA efforts to develop “cyberenvironments” that span scientific disciplines and that can rapidly evolve to incorporate new research results (Elnashai et al. 2008). An important aspect of ERGO is its extensibility, both in terms of analysis/features modules and of visualization/representation (GIS) modules. The framework has been designed to implement the consequence-based risk management (CRM) paradigm supported by the NCSA and MAE center.

Europe

Until now, no coordinated action for the development of a comprehensive methodology and software tool at European level is made. However, important efforts have been undertaken through research projects mainly funded by European Union. Brief description of the most important is following.

RISK-UE (2001–2004) project involved the assessment of earthquake scenarios based on the analysis of the global impact of one or more plausible earthquakes at city scale, within a European context. The primary aim of these scenarios was to increase awareness within the decision-making centers of a city. The developed methodology for creating earthquake scenarios focused on the distinctive features of European cities with regard to current and historical buildings and lifelines, as well as on their functional and social organization, in order to identify weak points within the urban system. The approach was applied to 7 European cities: Barcelona, Bitola, Bucharest, Catania, Nice, Sofia, and Thessaloniki (Mouroux and Le Brun 2006).

LESS-LOSS (2003–2007) was a European Integrated Project focusing on risk mitigation for earthquakes and landslides that relied on the active participation of 46 partners from both academia and industry. The project addressed research issues on seismic engineering, earthquake risk and impact assessment, landslides monitoring, mapping and management strategies, improved disaster preparedness and mitigation of geotechnical hazards, development of advanced methods for risk assessment, methods of appraising environmental quality, and relevant pre-normative research. Separate sections were devoted on earthquake disaster scenario predictions and loss modeling for urban areas and infrastructures with emphasis on water and gas systems (Faccioli 2007).

SYNER-G (2009–2013, www.syner-g.eu) is the most recent European funded research project that developed an integrated, general methodology and a comprehensive framework for the systemic vulnerability and risk analysis of buildings, lifelines, and infrastructures. The proposed methodology and tools encompass in an integrated fashion all aspects in the chain, from hazard to the vulnerability assessment of components and systems and to the socioeconomic impacts of an earthquake, accounting for most relevant uncertainties within an efficient quantitative simulation scheme and modeling interactions between the multiple component systems. It systematically integrates the most advanced fragility or

vulnerability functions to assess the vulnerability of physical assets. The increasing impact due to interdependencies and intra-dependencies between different components and among different interacting systems is treated in a comprehensive way, providing specifications for each network and infrastructure. The proposed socioeconomic model integrates social vulnerability into the physical systems modeling approaches providing to decision makers with a dynamic platform to capture post disaster emergency issues like shelter demand and health impact decisions (Pitilakis et al. 2014a, b).

Other Efforts Worldwide

The Central American Probabilistic Risk Assessment (CAPRA) platform was developed in partnership with Central American governments, the support of the Central American Coordination Centre for Disaster Prevention (CEPREDENAC), the Inter-American Development Bank (IDB), the International Strategy of United Nations for Disaster Reduction (UN-ISDR), and the World Bank. CAPRA is an information platform to enhance decision-making in risk management across various sectors, such as emergency management, territorial planning, public investment, and the financial sectors. Through the application of probabilistic risk assessment principles to threats like hurricanes, earthquakes, volcanic activity, floods, tsunamis, and landslides, CAPRA allows to measure and compare different types of risks and to develop sector-specific applications for risk management (Cardona et al. 2012; <http://www.ecapra.org/>). It is not directly designed for lifeline vulnerability and risk assessment, but it can be used for this purpose as well.

Key Elements of Seismic Risk Assessment

Risk assessment is the process used to determine risk management priorities by evaluating and comparing the level of risk to specific standards, either defined by a code or a set of target risk levels and criteria. The estimation of losses, both material and immaterial, is the ultimate target of the risk assessment. Then, the risk management procedure should define pre-seismic (retrofitting

and strengthening actions), coseismic, and post-seismic strategies and policies. The risk assessment of lifelines and infrastructures follows the general scheme of seismic risk assessment:

$$[\text{seismic risk}] = [\text{seismic hazard}] \times [\text{vulnerability}] \\ \times [\text{exposure} - \text{elements at risk}]$$

The complexity of elements at risk, their variability from one place and one country to another, and, till recently, the lack of well-validated damage and loss data from strong earthquakes make the vulnerability assessment of each particular component and of the network as a whole a challenging task. Adding to that the spatial extent of lifelines, the synergies between different systems, and the several sources of uncertainties that are inherent in the various aspects (e.g., typology, damage states), models (e.g., seismic hazard, spatial correlation, fragility curves), and finally tools and methods for estimation of losses, it is obvious that the risk assessment of lifelines is indeed a very complex and challenging issue. Therefore, multidisciplinary task and combined efforts are really needed to reach reliable and comprehensive estimates.

This difficulty is amplified due to lack of well-documented data and the partial or poor knowledge of the geometric and other features of the systems; in some cases it is also due to the confidentiality of data (i.e., communication or oil networks). The situation however has been improved the last decade. Important strong earthquakes provided valuable good quality data, while the public awareness and the reported huge direct and indirect losses associated to lifeline damages drew the attention of the scientific community, the governmental authorities, and the insurance sector. Moreover, the development of geographical information systems (GIS) as well as remote sensing technologies offered an excellent platform for the implementation of efficient and innovative techniques to screen, capture, store, manipulate, analyze, manage, and present geographical data.

Few terms employed in this chapter are described in the following. Inventory and

taxonomy/typology definitions of all elements at risk and systems are the necessary initial steps to describe the elements and networks exposed to seismic risk; at the same time, the development of detailed inventories is the most expensive task in terms of financial cost and time. The estimation of seismic hazard and site-specific seismic ground motion characteristics provides appropriate seismic intensity measures (IM), which will be used later in the vulnerability and loss assessment modeling. Vulnerability is the propensity of damage of an element (building, bridge, pipeline, roadway, oil tank, etc.) or a network of specific elements (e.g., water or gas system) to a given seismic intensity defined in the seismic hazard analysis. It is commonly assessed based on fragility models, which estimate the probability of damage for a given seismic intensity. Fragility functions are constructed with respect to the taxonomy and typological characteristics of each element at risk. The expected damages and losses of the entire network are estimated through a systemic analysis, which takes into account the physical damages of the various parts and segments of the system, and in some cases, the interdependencies between different components within the system and the interdependencies between systems, in order to estimate the serviceability or flow capacity of the damaged network. The results are commonly provided in terms of performance indicators (PI), which are describing the network functional or the expected economic or socioeconomic losses. Efficient risk management is based on the evaluation of the resulting performance indicator values.

Seismic Hazard for Distributed Networks

Lifelines are in most cases spatially distributed systems. Therefore, seismic hazard should meet the specific features of each system considering also its spatial variability. The vulnerability analysis and risk assessment must be evaluated according to the precise typological characteristics of the components and networks, taking also into account the models used to describe vulnerability, usually in terms of fragility curves and relationships. Moreover, due to the spatial extent of utility and transportation networks, the seismic

hazard should describe the spatial variability of ground motion considering local soil conditions, topographic effects, and geotechnical hazards; site-specific seismic hazard analyses are always necessary. Traditional seismic hazard analysis, while effective in translating the hazard into a probabilistic formulation, is limited in the extent to which it can incorporate spatial coherency of the form needed for estimation of loss to spatially distributed portfolios. The extension of seismic risk analysis to multiple systems of spatially distributed infrastructures presents new challenges in the characterization of the seismic hazard input, particularly with respect to the spatial correlation structure of the ground motion residuals (i.e., residuals from empirical intensity models) that form the basis for the systemic risk analysis.

A general procedure entitled “Shakefield” has been recently established in the frame of SYNER-G project (Pitilakis et al. 2014b), which allows for the generation of samples of ground motion fields both for single-scenario-type events and for stochastically generated sets of events needed for probabilistic seismic risk analysis (Weatherill et al. 2014). For a spatially distributed infrastructure of vulnerable elements, the spatial correlation of the ground motion fields for different measures of the ground motion intensity is incorporated into the simulation procedure. This is extended further to consider spatial cross-correlation between different measures of ground motion intensity.

The consideration of hazard from permanent ground deformation (PGD) is essential in modeling the seismic risk to lifeline systems. For pipelines and similar systems with linear elements, fragility models are generally given in terms of PGD, as they are mostly vulnerable to permanent displacement of the ground rather than transient shaking. Four primary causes of permanent ground displacements are commonly considered: liquefaction-induced lateral spread, liquefaction-induced settlement, slope displacement, and coseismic fault rupture. In addition to strong shaking, another transient effect that poses a potential risk to lifeline systems is the transient ground strain (PGS). Several models are available for the estimation of PGD; some of them are

intended to relate the degree of deformation and the probability of the geotechnical hazard occurring to the intensity of the ground motion (Weatherill et al. 2014). However, it should be noted that most theoretical and empirical models relating PGD to strong shaking require a level of geotechnical detail that may be impractical to obtain for a spatially distributed set of sites. HAZUS methodology (FEMA 2003) provides a rather simple “baseline” model that can be implemented in the widest variety of applications.

When the scenario type or probabilistic site-specific seismic hazard is available, the damage assessment of a lifeline system is evaluated using appropriate fragility or vulnerability functions relating the probability of damages to seismic intensity measures. The data and parameters needed to perform this analysis are shortly described in the following.

Taxonomy, Inventory, and Typology

The key assumption of the vulnerability assessment of lifelines is that the structures and components of the systems, having similar structural characteristics (e.g., a bridge of a given typology), being in similar geotechnical conditions (e.g., a segment of a pipeline crossing the same soil conditions and exposed to the same geotechnical hazards), are expected to perform in the same way for a given seismic excitation. Within this context, expected damages are directly related to the structural properties of the elements at risk. *Taxonomy* and *typology* are thus fundamental descriptors of a system that are derived from the inventory of each element and system. Geometry, material properties, morphological features, age, seismic design level, anchorage of the equipment, soil conditions, and foundation details are among usual typology descriptors/parameters. Buildings, bridges, pipelines (gas, fuel, water, wastewater), tunnels, road embankments, power substations, harbor facilities, and road and railway networks have their own specific set of typologies and different taxonomy.

The taxonomy of any lifeline network is thus an essential step for identifying, characterizing, and classifying all types of lifeline elements according to their specific typology and their

distinctive geometric, structural, and functional features. It allows the classification of the network elements in an ordered classification system adequate for the seismic risk assessment of each component and the network (or system) as a whole. The taxonomy is specific for each lifeline system and it needs a detailed typology definition of all elements at risk. For that, an adequate inventory process is essential. However, several difficulties arise in the collection and archiving of the data related to the absence of well-organized archives in public and often in private organizations managing the systems, the oldness of the networks (e.g., water network), and the high cost to draw up complete inventories. To this respect remote sensing techniques and GIS offer a useful and indispensable instrument and platform to enhance with relatively low cost the collection of the data and implement any inventory inquiries. Different types of satellite data can be used to extract information and parameters needed to compile or update inventories for seismic risk assessment. Examples include the width of roads, the geometry or material of buildings, building aggregates, infrastructures like bridges and channels, land use characteristics, and others.

The inventory of a specific structure in a region and the capability to create classes of structural types (e.g., with respect to material, geometry, and design code level) are among the main challenges when carrying out a general seismic risk assessment, for example, at a city or region scale, where it is practically impossible to perform this assessment separately for each single structure. It is necessary to classify all elements at risk, in “as much as possible” homogeneous classes and subclasses presenting more-or-less similar response characteristics to ground shaking. Thus, the derivation of appropriate fragility curves for any type of structure depends entirely on the creation of a reasonable taxonomy that is able to classify the different kinds of structures and infrastructures in any system exposed to seismic hazard. Several uncertainties are inherent to each taxonomy system, which are inevitably propagated through the generic fragility (vulnerability) curves to the final loss estimation. The most coherent and

comprehensive taxonomy presently available in Europe is produced in SYNER-G project (Table 1, Pitilakis et al. 2014a). Detailed classifications are also provided in HAZUS (FEMA 2003) and ALA (2001).

Each component is further classified according to its specific features regarding its seismic behavior. For instance, the main typological features of gas pipelines include the material type, material strength, diameter, wall thickness and smoothness of coating, type of connection and joints, as well as the nominal design and actual flow. Among them, material and the connection types (joints) together with the soil type are the most critical parameters for their seismic response. Table 2 outlines common types of pipelines based on the above classification criteria.

Another example is storage tanks, which are usually categorized according to their material type (steel or reinforced concrete), construction type (at grade or elevated), anchorage (anchored or unanchored), roof type and capacity, shape factor (height-on-diameter ratio), and amount of content in the tank (full, half full, empty). Among them, material type, construction type, and anchorage are considered as the most important. Table 3 presents the classification of tanks in USA according to ALA (2001).

For a systematic and detailed description of all classes and subclasses of all elements at risk in most lifeline systems and networks in the European context, the reader should refer to Pitilakis et al. (2014a).

Damage Assessment

The damage patterns and mechanisms are different for each lifeline system and element (component), and they are strongly depending on the typology of each structure (i.e., materials, geometry, structural types). For example, the damage mechanisms of pipelines are generally classified in the form of breaks or leaks; material type (i.e., brittle or ductile) and joints (i.e., flexible or rigid) are also factors affecting the seismic response and damages of pipelines. In case of tunnels, damage patterns include lining cracks (longitudinal or transverse) and spalling, wall

Seismic Vulnerability Assessment: Lifelines, Table 1 SYNER-G infrastructure taxonomy (Pitilakis et al. 2014a)

System	Component (and subcomponents)
BDG: buildings	Force-resisting mechanism (FRM1): moment-resisting frame structural wall, flat slab, bearing walls, precast, confined masonry
	FRM material (FRMM1): concrete, masonry
	Plan (P): regular, irregular
	Elevation (E): regular/irregular geometry
	Cladding (C): regular infill vertically, irregular infill vertically, bare
	Detailing (D): ductile, non-ductile, with tie rods/beams, without tie rods/beams
	Floor system (FS): rigid, flexible
	Roof system (RS): peaked, flat, gable end walls
	Height level (HL): Low rise, mid-rise, high rise, tall
	Code level (CL): none, low, moderate, high
EPN: electric power network	EPN01: electric power grid
	EPN02: generation plant
	EPN03: substation
	EPN04: distribution circuits
	EPN05–09: substation macro-components (autotransformer line; line without transformer; bar-connecting line; bars; cluster)
	EPN10–23: substation micro-components (circuit breaker; lightning arrester or discharger; horizontal disconnect switch or horizontal sectionalizing switch; vertical disconnect switch or vertical sectionalizing switch; transformer or autotransformer; current transformer; voltage transformer; box or control house; power supply to protection system; coil support; bar support or pothead; regulator; bus; capacitor tank)
	EPN24: transmission or distribution line
GAS: natural gas system	GAS01: production and gathering facility (onshore, offshore)
	GAS02: treatment plant
	GAS03: storage tank
	GAS04: station (compression; metering/pressure reduction; regulator; metering)
	GAS05: pipeline
	GAS06: SCADA
OIL: oil system	OIL01: production and gathering facility (onshore, offshore)
	OIL02: refinery
	OIL03: storage tank farm
	OIL04: pumping plant
	OIL05: pipeline
	OIL06: SCADA
WSS: water-supply network	WSS01: source (springs, rivers, natural lakes, impounding reservoirs, shallow or deep wells)
	WSS02: treatment plant
	WSS03: pumping station
	WSS04: storage tank
	WSS05: pipe
	WSS06: tunnel
	WSS07: canal
	WSS08: SCADA system
WWN: wastewater network	WWN01: wastewater treatment plant
	WWN02: pumping (lift) station
	WWN03: pipe
	WWN04: tunnel
	WWN05: SCADA system

(continued)

Seismic Vulnerability Assessment: Lifelines, Table 1 (continued)

System	Component (and subcomponents)
RDN: road network	RDN01: bridge (material, type of deck, deck structural system, pier to deck connection, type of pier to deck connection; type of section of the pier, spans, type of connection to the abutments, skew, bridge configuration, foundation type, seismic design level)
	RDN02: tunnel
	RDN03: embankment (road on)
	RDN04: trench (road in)
	RDN05: unstable slope (road on or running along)
	RDN06: road pavement (ground failure)
	RDN07: bridge abutment
RWN: railway network	RWN01: bridge
	RWN02: tunnel
	RWN03: embankment (track on)
	RWN04: trench (track in a)
	RWN05: unstable slope (track on or running along)
	RWN06: track
	RDN07: bridge abutment
HBR: harbor	RWN08: station
	HBR01: waterfront components (gravity retaining structures; sheet pile wharves; piers; breakwaters mooring and breasting dolphins)
	HBR02: earthen embankments (hydraulic fills and native soil material)
	HBR03: cargo handling and storage components (cranes, tanks, etc.)
	HBR04: buildings (sheds, warehouse, offices, etc.)
FFS: fire-fighting system	HBR05: liquid fuel system (as per the OIL system)
	FFS01: fire-fighter station
	FFS02: pumping station
	FFS03: storage tank
	FFS04: fire hydrant
	FFS05: pipe

deformation, bending and buckling of reinforcing bars, obstruction of the opening, or pavement cracks. In subway stations damages to columns may also occur. Damages to quay walls are related to excessive lateral pressures or decrease of shear strength of the foundation soil that can cause sliding, deformation, and tilting of the walls. Settlements and lateral movement of the backfill materials and cracking of apron pavements can be also induced. Damage to electric power substations includes failures of the various subcomponents (e.g., disconnect switches, circuit breakers, transformers) or damage of the building. Earth structures such as highway and railway embankments can spread laterally and settle, resulting in opening of cracks in the road pavement or displacement of the railway tracks. The list of possible damage patterns is unlimited.

Therefore, classification of damage and the subsequent definition of specific damage states are important in the vulnerability assessment as the seismic intensity is correlated to the expected damage level through the fragility or vulnerability functions. Again, the form of the fragility functions depends on the typology of the element at risk. For common structures (e.g., buildings, bridges) and other not extended elements (e.g., cranes, tanks, substations), the fragility curves describe the response and damage level of particular subcomponents (e.g., columns, transformers) or of the entire structure. For linear elements of extended networks such as gas pipelines, the fragility functions describe the number of expected damages along a certain length (i.e., per km). Examples and further details are given in the next sections.

Seismic Vulnerability Assessment: Lifelines, Table 2 Common types of materials and connections for buried pipelines

Material type	Connection type
Asbestos cement (AC)	Arc welded
Cast iron (CI)	Bell and spigot
Ductile iron (DI)	Cemented
Concrete (C)	Riveted
Polyvinyl chloride (PVC)	Rubber gasket
Welded steel (WS)	Gas welded
Medium-density polyethylene (MDPE)	
High-density polyethylene (HDPE)	

Damage States

In seismic risk assessment, the performance levels of a structure, for example, a reinforced concrete building, belonging to a specific class (Pitilakis et al. 2014a) can be defined through damage thresholds called limit states. A limit state defines a boundary between two different damage conditions often referred to as *damage states*. The thresholds are related to functionality and serviceability levels while they are usually defined based on engineering judgment and common sense. They are also strongly depending on the model applied for the analysis and derivation of the fragility functions. Uncertainties related to this stage of the analysis are normally referred as epistemic uncertainties (see Pinto 2014). Different damage criteria have been proposed depending on the typologies of elements at risk and the approach used for the derivation of fragility curves. The most common way to define earthquake consequences is a classification in terms of the following damage states: *no damage*, *slight/minor*, *moderate*, *extensive*, and *complete*. This qualitative approach requires an agreement on the meaning and the content of each damage state. The number of damage states is variable and is related with the functionality of the components and/or the repair duration and cost. In this way the total losses of the system (economic and functional) can be estimated. In particular, physical damages are related to the expected serviceability level of the component (i.e., fully or partial operational or inoperative) and the

Seismic Vulnerability Assessment: Lifelines, Table 3 Typology of tanks (ALA 2001)

Unanchored redwood tank (5×10^4 – 5×10^5 gal)
Unanchored post-tensioned circular concrete tank ($>1 \times 10^6$ gal)
Unanchored steel tank with integral shell roof (1×10^5 – 2×10^6 gal)
Unanchored steel tank with wood roof (1×10^5 – 2×10^6 gal)
Anchored steel tank with integral steel roof (1×10^5 – 2×10^6 gal)
Unanchored steel tank with integral steel roof ($>2 \times 10^6$ gal)
Anchored steel tank with wood roof ($>2 \times 10^6$ gal)
Anchored reinforced (or prestressed) concrete tank (5×10^4 – 1×10^6 gal)
Elevated steel tank with no seismic design
Elevated steel tank with nominal seismic design
Open-cut reservoir
Fiberglass tanks

corresponding functionality (e.g., power availability for electric power substations, number of available traffic lanes for roads, flow or pressure level for water system). These correlations provide quantitative measures of the component’s performance and can be applied for the definition of specific *performance indicators (PIs)*, which are introduced in the systemic analysis of each network. Therefore, the comparison of a demand with a capacity quantity, the consequence of a mitigation action, or the accumulated consequences of all damages (usually referred as the “impact”) can be evaluated.

Methods for deriving *fragility curves* generally describe damages on a discrete damage scale. In the empirical procedures, the scale is used in survey efforts to produce post-earthquake damage statistics, and sometimes it is rather subjective (i.e., there is often a discrepancy between the damage levels that any two different inspectors would assign for the same incident). In analytical procedures the scale is related to limit state of selected mechanical properties that are described by appropriate indices, such as the displacement capacity or the storey drift in the case of buildings or simple drift in pier bridges. For other elements at risk, the definition of the performance levels or the limit states may be more vague and follows

other criteria related, for example, in the case of pipelines, to the limit strength characteristics of the material used in each typology. The definition and consequently the selection of the damage thresholds, i.e., limit states, are among the main, yet, unavoidable sources of uncertainties.

Intensity Measures

An important issue related to the fragility curve construction and implicitly to the risk assessment is the selection of an appropriate earthquake *intensity measure (IM)* that characterizes the strong ground motion that best correlates with the response of each element, for example, building, pipeline, or harbor facilities like cranes. Several measures of the intensity of ground motion (IMs) have been developed. Each intensity measure may describe different characteristics of the motion, some of which may be more adverse for the structure or the system under consideration. The use of a particular IM in seismic risk analysis should be guided by the extent to which the measure corresponds to damage to the components of a system. Optimum intensity measures are defined in terms of practicality, effectiveness, efficiency, sufficiency, robustness, and computability (Mackie and Stojadinovic 2003).

In general, IMs are grouped in two general classes: empirical intensity measures and instrumental intensity measures. With regard to the empirical IMs, different macroseismic intensity scales could be used to identify the observed effects of ground shaking over a limited area. Instrumental IMs are, by far, more accurate and representative of the seismic intensity characteristics and the severity of ground shaking. For example, for bridges the best descriptor is a spectral response value at a specific period (i.e., $T = 1.0$ s). For other lifeline components, it may be the peak ground acceleration (e.g., buildings, tanks, electric power substations), peak ground velocity (e.g., pipelines), or even the permanent ground deformations (e.g., pipes, embankments, roadways, railways). The correlation between damages of specific elements at risk and intensity measures is not simple and never unique. Several other descriptors like peak ground strain, Arias intensity, cumulative absolute velocity, and other

parameters of the ground motion have been also used for different structures composing a lifeline system. More recently, it is proposed to use two descriptors instead of one, and hence the fragility curve is transformed in fragility surfaces (Seyedi et al. 2010; Douglas et al. 2014).

The selection of the adequate intensity parameter is also related to the approach that is followed for the derivation of fragility curves and the typology of elements at risk. The identification of the proper IM is determined from different constraints, which are first of all related to the adopted hazard model, but also to the element at risk under consideration and the availability of data and fragility functions for all different exposed assets. Empirical fragility functions are usually expressed in terms of the macroseismic intensity defined according to different macroseismic scales (EMS, MCS, and MM). Analytical or hybrid fragility functions are, on the contrary, related to instrumental IMs, which are related to parameters of the ground motion (PGA, PGV, PGD) or of the structural response (spectral acceleration S_a or spectral displacement S_d , for a given value of the period of vibration T). When the vulnerability of elements due to ground failure is examined (i.e., liquefaction, fault rupture, landslides), permanent ground deformation (PGD) is the most appropriate IM.

Vulnerability Assessment and Fragility Curves

The fundamental tool in seismic risk assessment of lifeline components is the *fragility curves* which describe the probability that a structure will reach or exceed a certain damage state for a given ground motion intensity. An extensive review of available fragility functions and state-of-the-art methods for vulnerability assessment of buildings and lifeline components can be found in Pitilakis et al. (2014a). Fragility curves are usually represented by two-parameter (median and log-standard deviation) cumulative lognormal distributions. Several approaches are used to establish fragility functions. They are grouped in the following five categories:

- Empirical fragility curves, based on post-earthquake surveys and observations of actual

Seismic Vulnerability Assessment: Lifelines,

Fig. 9 Empirical fragility curves for power grids made up of substations of different voltages based on data from US west coast earthquakes (Dueñas-Orsorio et al. 2007)

damage. They are specific to particular sites and seismotectonic, geological, and geotechnical conditions, as well as the properties of the damaged structures. Consequently, the use of these functions in different regions is always questionable (Figs. 9 and 10).

In case of pipelines, the empirical fragility functions relate the repair rates (RR) expressed as repairs/km with the peak ground velocity (PGV) or permanent ground deformation (PGD) (Fig. 11). The curves may be further adapted to the material properties and geometry of the pipelines and soil conditions. In the last two decades, the increased density of high-quality strong ground motion records in different soil conditions, in combination with new technologies such as geographical information systems (GIS) and remote sensing technologies (e.g., LiDAR) capable to measure more accurately ground movements, contributed significantly to the development and verification of such relationships (O'Rourke et al. 2012).

- Analytical fragility curves, based on numerical simulations of structural models under increasing earthquake loads (Figs. 12 and 13). Analytical methods, validated with large-scale experimental data and observations from recent strong earthquakes, have become more popular in recent years.

The main reason is the considerable improvement of computational tools, methods, and skills, which allows comprehensive parametric studies covering most common typologies to be undertaken. Moreover, several of the associated uncertainties, e.g., material properties, are better controlled.

- Judgmental or expert elicitation fragility curves, using questionnaires by which the experts are queried on the probability of a component being in a certain damage state for a given intensity (Fig. 14). They are versatile and relatively fast to establish, but their reliability is questionable because of their dependence on the experiences of the experts consulted.
- Hybrid fragility curves, which combine any of the above-mentioned techniques in order to compensate for their respective drawbacks.
- Fragility curves based on a fault-tree analysis, where complex components (e.g., substations, pumping plants, hospitals) are broken down into subcomponents and the global fragility is obtained based on the relationships between the subcomponents and their individual fragilities (Fig. 15).

An example of damage estimation for “on-ground unanchored steel tanks” due to ground shaking and “pipelines” due to ground failure is given in Table 4. In the first case, the exceedance probabilities of each damage state are estimated

Seismic Vulnerability Assessment: Lifelines,

Fig. 10 Empirical fragility curves for on-ground steel tanks subjected to ground shaking (ALA 2001)

based on the fragility curves in Fig. 10, and then the punctual probabilities of each damage state are obtained. In the second case, the repairs per kilometer are estimated for a given value of PGD based on the curves in Fig. 11. The estimated repairs should be modified according to the length of the pipe segment under study.

Systemic Analysis

The majority of the methodologies that have been developed worldwide for the seismic risk assessment of lifelines and infrastructures refer to single systems, without considering interactions, cascading failures, and complex impacts. The study of interdependent infrastructures is challenging due to heterogeneous quality and

insufficient data availability and the need to account for their spatial and temporal aspects of complex supply–demand operation (Satumtira and Duenas-Osorio 2010). The various approaches available in the literature depend on the simulation method, modeling objectives, scale of analysis, availability of input data, and end-user type or needs. A comprehensive categorization scheme describing different levels is provided in Modaressi et al. (2014):

- Vulnerability analysis: This level considers only the potential physical damages of the components of the systems, with no consideration of functionality of either the elements or the whole system.

Seismic Vulnerability Assessment: Lifelines,

Fig. 11 Empirical fragility functions for common pipeline typologies provided by ALA (2001): (a) pipelines subjected to wave propagation (PGV), (b) pipelines subjected to permanent ground deformation (PGD)

- Connectivity analysis: This level describes the probability of the demand nodes to be connected to functioning supply nodes through undamaged paths. In this approach the damaged components are removed from the network and the adjacency matrix is updated accordingly, thus pointing out the nodes or areas that are disconnected from the rest of the system. This qualitative approach is used for all utility networks (water, electricity, gas) and the road transportation system.
- Capacitive analysis: This level describes the ability of the system to provide to the users the required functionality through a quantitative approach. For utility networks, graph algorithms and flow equations can be used to

estimate capacitive flows from sources (e.g., generators, reservoirs) to sinks (i.e., distribution nodes), based on the damages sustained by the network components (from total destruction to slight damages reducing the capacity).

- Fault-tree analysis: This level of analysis concerns critical infrastructures, where multiple conditions are necessary for the systems to ensure its task. This type of approach aims to evaluate the remaining operating capacity (residual operation capacity) of objects such as health-care facilities. The system is broken down into structural, nonstructural, or human components, each one of them being connected with logic operators.

Seismic Vulnerability Assessment: Lifelines,

Fig. 12 Analytical fragility curves for alluvial bored tunnels due to ground shaking, classified to ground type *B*, *C*, and *D* according to Eurocode 8 (Argyroudis and Pitilakis 2012)

Seismic Vulnerability Assessment: Lifelines,

Fig. 13 Analytical fragility curves for gravity waterfront structures due to ground shaking, classified according to the wall height (H) and the soil foundation conditions (Vs values) (Kakderi and Pitilakis 2010)

Seismic Vulnerability Assessment: Lifelines,

Seismic Vulnerability Assessment: Lifelines,

Fig. 15 Fault-tree based fragility curves for water treatment plant with anchored components subjected to ground shaking (Pitilakis et al. 2014a)

Seismic Vulnerability Assessment: Lifelines, Table 4 Example of damage estimation for steel tanks and pipelines

	On-ground unanchored steel tanks subjected to ground shaking (PGA = 0.4 g)				
Damage state	No damage	Minor	Moderate	Extensive	Complete
Probability of exceedance	–	0.919	0.571	0.240	0.108
Probability of occurrence	0.081	0.348	0.331	0.132	0.108
	(=1–0.919)	(=0.919–0.571)	(=0.571–0.240)	(=0.240–0.108)	
	Pipelines subjected to ground failure (PGD = 40 cm)				
Material diameter	Welded steel – large		Welded steel – small		PVC – small
Repairs/km	1.26		5.86		6.70

The performance of each network (e.g., utility or accessibility losses) is commonly measured through appropriate *performance indicators (PIs)*, which, if combined with direct losses from physical damages, can yield a first partial estimate of the overall socioeconomic impact of an earthquake. Performance indicators, at the component or the system level, depend on the type of analysis that is performed. Connectivity analysis gives access to indices such as the connectivity loss (measure of the reduction of the number of possible paths from sources to sinks). Capacitive modeling yields more elaborate performance indicators at the distribution nodes (e.g., head ratio for water system, voltage ratio for electric buses) or for the whole system (e.g., system serviceability index comparing the customer demand satisfaction before and after the seismic event). The fault-tree analysis method is generally used for the derivation of fragility

curves for specific components that comprise a set of subcomponents (e.g., health-care facilities, water treatment plants).

The importance of the interconnection between different systems is a more recent acquisition that targets two or, rarely, more systems (Pitilakis et al. 2014b). Several classifications have been proposed to categorize the types of interactions. The most common are physical, demand, and geographic interactions (Rinaldi et al. 2001). Physical interaction describes physical reliance on material flow from one infrastructural system to another as, for example, the supply of power to various network facilities by electric generators. Demand interactions correspond to a supply–demand from a given component to another system. An example is the number of casualties that should be treated by health-care facilities after an earthquake. Finally, geographic interactions describe the way that a local

environmental event affects components across multiple infrastructural systems due to physical proximity. For instance, the collapse of buildings in city centers can induce the blockage of adjacent roads due the debris accumulation.

A comprehensive methodological framework for the assessment of physical as well as socio-economic seismic vulnerability and risk of buildings, lifelines, and infrastructures at urban and regional level considering inter-element and intra-systems dependencies has been developed in SYNER-G project. The reader is referred to Pitilakis et al. (2014b) for more details and applications of the proposed framework.

Seismic Risk Assessment of Lifelines:

Examples

Representative examples of seismic risk assessment studies for lifelines are given in the following, for different scales of analysis.

Medium- to High-Voltage Electric Power Network of the Sicily Region, Southern Italy (Regional Scale)

A power flow analysis is performed for the electric power network of Sicily, which is composed of 181 nodes and 220 transmission lines (Cavalieri et al. 2014). The nodes, i.e., the buses, are subdivided into 175 demand or load nodes and six supply nodes, five of which are power plants and one is the balance node (or slack bus), which is coinciding with the generation node providing the highest power. The load nodes (two for transmission/distribution and one for distribution substations) deliver power to users. In total, 390 municipalities are served by the network. All transmission lines are overhead lines and considered as non-vulnerable elements. They are classified into high- (HV), medium- (MV), and low-voltage (LV) lines (Fig. 16a). The vulnerable elements are the components within substations, called micro-components. A probabilistic evaluation of the performance of network is carried out by means of Monte Carlo simulation by sampling seismic events for 18 faults taken from the Italian DISS database employing the truncated Gutenberg and Richter recurrence model for the source activity.
